1 EXECUTIVE SUMMARY

The hard wood saw mill industry in Australia generates large volumes of wood residue in the form of chip, bark and sawdust, and understandably it is keen to use this to increase revenue streams. The Carnot Group has been engaged by the Forest & Wood Products Australia (FWPA), on behalf of the industry, to examine options for producing revenues from sawmill residues.

The following physical/chemical attributes of wood can be used as the basis of revenue generation:

- Stored chemical energy: conversion into thermal, electrical or kinetic energy
- Source of hydrocarbons: conversion into useful chemicals
- Mechanical properties of the fibrous cellulosic structure
- Source of organic material for biological feed
- Use of thermal or acoustic insulation properties

There are various processes for turning these attributes into useful products that can provide revenue streams. These include:

- Combustion: using the heat, via a heat transfer medium, for power generation and heating
- Gasification: using the syngas to fuel a boiler or IC engine for power generation or to produce bio-fuels
- Pyrolysis: to produce bio-oil or char products
- Pelletising: a dense fuel for domestic heating and fuelling small scale power plant
- Hydrolysis and fermentation: production of ethanol
- Various combined thermal and chemical processes: production of chemicals

Associated with the processes are technologies that are more or less developed to commercial readiness. The capital and operating costs of processing plant will strongly influence any decision to take a particular route to a marketable product. The other major consideration must be the size and maturity of the relevant markets for the products. Additionally, state and federal government incentives are currently available and new schemes are constantly under consideration for a range of renewable energy applications. In the main, these are related solely to the production of electricity.

Perhaps the most well known use of wood residues is in “waste to energy”, where the wood is combusted (directly or via gasification) for subsequent use in power plant producing electrical energy and often useful amounts of heat. This employs mature technologies such as boilers, steam engines and generators.

In these power plants the critical factors with taking this route are to ensure that sufficient wood waste is available to fuel the boiler or gasifier; that the electrical power can be used (possibly via an off-take agreement) and there is a match between demand and supply. The capital cost of plant with capacity of 5 to 10MW_e is in the range $2 to 3.5million per MW_e and operating costs of order $60 per MWh_e.
It is quite probable that any one mill will not have sufficient wood to fuel a power plant of reasonable size (and thus be economically viable) and in this case a number of mills could consider combining their residues. This action will be strongly influenced by the cost of transport between sites which is estimated at $10 per tonne for a 100km round trip. Also, in this case it is advantageous to increase the bulk density of the residue to maximise the weight of material carried per load. This can be done by processing the residues into pellets at a cost of approximately $6 to 8 per tonne. At the present time there is a small market for pellets in Australia however there is a potentially large export market, if economic shipping rates can be secured.

Consideration could be given to the future production of agri-char. This product is made by the pyrolysis (and possibly subsequent gasification) of wood to produce a dense carbon rich solid. There are indications that agri-char may be very effective for the enhancement of soils for agriculture. Agri-char may also be an effective means of long term carbon sequestration. Trials to prove the effectiveness are being carried out in Australia and globally.

The energy density of wood can be concentrated by converting it to a bio-fuel, such as ethanol and bio-oil. Ethanol from food crops such as corn, wheat and sugar cane is made in large volumes overseas and increasingly in Australia. There is extensive research into its production from ligno-cellulosic materials such as wood. It appears that the commercial scale production of ethanol from wood is roughly 5 to 10 years away. Bio-oil is more advanced and is currently produced from wood feedstock in commercial plants in Canada which is then converted to useful chemicals, most significantly industrial resins and food flavourings. A small commercial scale plant is being planned in Darwin to produce bio-oil from 200 tonnes per day of wood waste, which will then be used to generate electricity. There is no established market for bio-oil in Australia, but markets for industrial resins may be readily accessible.

The manufacture of a range of chemicals from wood via other process routes is technically feasible, but is still at research stage.

The benefits and commercial readiness of the various products that can be obtained from wood waste is summarised in the ‘value matrix’ shown below:

<table>
<thead>
<tr>
<th>Economic Benefit</th>
<th>Technology Readiness</th>
</tr>
</thead>
<tbody>
<tr>
<td>Low</td>
<td>Low</td>
</tr>
<tr>
<td></td>
<td>Platform chemicals</td>

<tr>
<td></td>
<td>Chemical products</td>
</tr>
<tr>
<td></td>
<td>Bio-fuels</td>
</tr>
<tr>
<td></td>
<td>CHP</td>
</tr>
</tbody>
</table>

Whilst the value matrix is somewhat subjective it is apparent that the products that provide for immediate possible sources of revenue from sawmill residues are heat and electrical...
power generation. The major equipment needed, such as boilers, gasifiers and gas filters will likely be supplied by overseas companies and installed and supported by local industry. At this time there are no commercial scale wood fired power plants operating consistently in the country. This is due in no small part to the lack of a sufficient volume and reliable supply of wood biomass at the right price. Also, in recent times, it has been difficult to entice overseas suppliers with tried and tested equipment to supply into Australia.

As time progresses, a number of factors can impact on the viability of all these options. Important factors are the changing government position on CO₂ reduction, increasing prices for fossil fuels, government desire for energy security, changing attitudes to waste disposal and advancements in relevant technologies.

Datasheets have been provided in Appendix II for the options found to be most technologically ready:

- Briquetting
- Pelletising
- Electricity or CHP via steam turbine
- Electricity or CHP via reciprocating steam engine
- Electricity or CHP via gasification and internal combustion engine

These data sheets are intended to be an easy reference tool for sawmill operators to quickly assess the suitability of these options for their particular circumstances.
2 INTRODUCTION

The aim of this report is to identify opportunities for using residues from normal sawmill activities, predominantly focusing on hardwood mills. In Australia, hardwood mills are generally small scale and scattered around the country. The softwood mills are generally larger and more highly integrated with other wood processing facilities.

Opportunities of interest will yield economic benefit either for a specific business or a collective. Economic benefits may involve reduction in operating costs, through the provision of cheaper heat and/or electricity, or new revenue streams, by value adding to wood residues. There is also a growing desire socially and within government and regulatory bodies to recycle, re-use and reduce waste going to landfill.

Forestry and Wood Products Australia, on behalf of the sawmill industry, has engaged The Carnot Group to examine options for producing revenue streams from sawmill residues. The Carnot Group is an engineering firm based in Melbourne, with a background in renewable energy.

2.1 Background

When a log is received into a saw mill only portions of its cross section are suitable for use as structural timber. The remaining streams of wood waste may consist of bulk pieces, hogged wood, sawdust, shavings, trimmings, bark and woodchips.

Estimating the volume of mill residues available for further processing is difficult. Recovery rates vary from location to location depending upon the dominant species processed, standard of processing equipment, log quality, production methods, grading, storage, drying and level of horizontal and vertical integration. The recovery rate is especially dependent on log dimensions. For logs in the range of 30 to 70 cm in diameter, recovery rates drop to about half when the log diameter is halved.1

Waste or mill by-products can then be categorized by six main attributes:

- Species
- Segregation (species mixture)
- Purity (clean or contaminated)
- Moisture content
- Storage (in silos, bins or left on the ground)
- Size

These attributes are important when considering potential uses for the waste. A wet log processed by a sawmill would typically produce the following residue quantities by weight after de-barking 2:

- Bark – 6 %
- Sawdust – 7%
- Shavings – 5%
- Woodchips – 35%
2.2 Current Disposal Practices

The waste streams from sawmills are increasingly put to a wider variety of uses. Nowadays, some softwood mills are able to sell or use practically all of their waste streams, meaning almost no product gets dumped. Typical uses for sawmill residues are shown in Table 1.

<table>
<thead>
<tr>
<th>By-product</th>

</tr>
<tr>
<td>Sawdust</td>
<td>Mainly kiln, some soil amendment, animal bedding</td>
</tr>
<tr>
<td>Shavings</td>
<td>Soil amendment, kilns and boilers, animal bedding</td>
</tr>
</tbody>
</table>

Wood chips are either sold for domestic pulping or exported for a price of $35 to $60 per tonne. Bark is primarily mulched and used as a soil amendment product or composted. The revenue for bark is generally $10 to $30 per tonne.

There are still sawmills where some or all residues are either dumped or burnt for no useful purpose, particularly hardwood mills which are generally smaller in size than softwood mills.

2.3 Sawmill Energy Requirements

The energy usage between sawmills varies widely since no two sawmills are alike. Sawmills normally use electrical energy to drive motors for a variety of operations, many also perform kiln drying, using large quantities of heat, as shown in Table 2. It is clear that a considerable amount of energy is used when kiln drying is employed.

a. applicable to kiln drying and not air drying

It is pertinent to note that in Australia in 1999, timber residues from sawmills and material that was not chipped for export or used for board products was estimated to have an energy equivalency of about 120 PJ per yr (1PJ = 1 million MJ). At a conversion efficiency of 30% that would generate about 10,000 GWh of electricity annually. In practice though, only a fraction of this resource could be economically used for electricity generation.
The use of biomass to displace fossil fuel derived energy is of growing interest and there are government incentives to increase the generation of renewable and carbon neutral energy. The CO₂ emissions brought about in generating sawmill electricity and drying heat have been estimated and are shown in Table 3 below; however these values are dependent on the energy source from which it was derived.

**Table 3: Estimated CO₂ emissions (x1000 tonnes per year) from a typical hardwood sawmill (20,000 m³ per year of finished timber product) including kiln drying.**

*Note: The electricity is assumed to be normal grid procured power. Heat is assumed to be derived from combustion of natural gas. Emission estimates take into account energy involved in fuel handling, generation and distribution costs.*
3 TECHNOLOGY OPTIONS

3.1 Overview
The practical uses for sawmill residues may be grouped in many ways, however most applications utilize one or more of the intrinsic material properties of wood as follows:

- Conversion of stored chemical energy into thermal, electrical or kinetic energy
- As a source of hydrocarbons for useful chemicals
- Employing the mechanical properties of the fibrous cellulosic structure
- As a source of organic material for biological feed
- Use of thermal or acoustic insulation properties

There is a long list of products that can be derived from sawmill residues, employing an array of different technologies. Energy products are among the most appealing options at present, due to mounting social and political pressure to reduce Greenhouse Gas (GHG) emissions. The combustion of biomass for energy is recognised under the Kyoto Protocol as being neutral in terms of GHG emissions. Wood combustion may be exploited to reduce GHG emissions and potentially attract economic benefits through government incentives. Energy may be derived from woody biomass in a number of different forms, including:

- Heat in hot gases or steam
- Electricity
- Bio-fuels and bio-oils
- Solid fuels - compressed wood (pellets or briquettes) or charcoal briquettes

Each of these energy products may be produced via a number of process routes or technologies, as illustrated in Figure 1 below. There are also other non-energy products such as agri-char, activated carbon and a long list of chemicals, presenting a complex set of options and opportunities. The paths and products below the dashed line are considered, for the purposes of this report, to be largely established technologies and are not discussed in detail.
Figure 1: Potential technologies for the conversion of sawmill residues into useful products.

Note: The pre-processing required for each method is not shown but may not be equivalent for each route. For example, many of these applications require the wood waste to be separated from other wastes, cleaned and processed (grinding or chipping).

The sections below provide a description of these technologies and their state of maturity, in relation to sawmill residues.
Pre-treatment - Size Reduction and Drying

Essentially all the technology options discussed in this report for using sawmill residues require some degree of size reduction of the wood together with drying. Size reduction via hogging, chipping, grinding, etc, requires mechanical energy usually provided by electrical motors or internal combustion engines. Drying too requires energy, and may be provided by solar, natural convection, mechanical pressing or heating. These processes can be energy intensive and expensive.

The energy required to grind wood is dependent on many variables relating to the equipment used, the characteristics of the wood and the degree of size reduction. The energy requirements for size reduction is difficult to measure accurately, but has been reported for some different applications in Table 4 below. The consumption of energy increases exponentially with decreasing particle size.

An improvement in the ability to grind biomass through torrefaction (thermal treatment in temperature range of 200 to 300°C) was observed by Bergman et al. 11. It was found that the energy for size reduction can be decreased by 50 to 85% and throughput increased by a factor of 2 to 6.5 after torrefaction, compared to untreated biomass. Additionally, as the fibrous structure of biomass is partly destroyed, the material is more easily fluidised assisting in pneumatic conveying and entrained air gasification. Around 83 to 97% of the original energy (LHVdaf) is retained in the torrefied wood with reaction times of less than 10 min. The lost energy corresponds to 0.36 to 2.04MJ per tonne. This approach may be suitable in certain cases and basically involves trading capital and operating costs on grinding equipment with capital and operating costs on up front torrefaction.

To remove moisture from very wet biomass, mechanical drying (eg, centrifuging, pressing) may be used to reduce moisture content to about 50% w.b. (wet basis). To reduce moisture content below 50% w.b. requires thermal or forced convection drying. A modern thermal dryer uses about 5 to 10MJ of energy for the evaporation of 1 kg water. This means that decreasing the moisture content by approximately 10% consumes about 3.5% to 7% of the heating value of the dry material. When local conditions of solar availability and humidity permit, solar drying is an appealing alternative.

It is tempting to implement forced drying of biomass by using waste low grade heat from other processes such as flue gases, steam heat recovery heat exchangers, timber kiln exhaust, etc. These approaches may be advantageous in certain circumstances, but involve additional capital and operating costs in ducting, fans, drying silos, safety systems and control systems. In general, excess heat in flue gases is much more economically used in the preheating of combustion air. Dryers are expensive to install and even more expensive to maintain, present a serious fire hazard, and increase the suspended particulate loading in the flue gas.
3.3 Compressed Fuels for Burning

An option for using fine wood waste is compressing it into pellets or briquettes to be used as a dense, solid fuel source for stationary heat and power applications. Compression of fine and loose sawmill residues will create a solid fuel that is easier to convey and transport and has a higher, uniform volumetric energy density.

Pellets are small highly compressed wood slugs that can be produced on a large scale and are used widely. Briquettes are larger products that can be manufactured at smaller scales for moderate costs, but are less widely used. Pellet and briquette products can be made from both hardwoods and softwoods.

3.3.1 Wood pellets

TECHNOLOGY DESCRIPTION

Wood pellets, shown in Error! Reference source not found., are made from compressed dry sawdust, with the assistance of steam or a binder such as starch. The pellets can be made in a range of sizes depending on their required final application and market. Pellet markets generally require pellets to conform to a strict standard, which stipulates that pellets should be dry (moisture content typically less than 7% w.b.), mechanically robust and have an ash content and may also define other contaminants levels such as chlorine content. Pellets should also flow freely and be able to be delivered via a pneumatic system. The Australian and New Zealand standard for wood pellets is AS/NZS 4014.6:2007 and there are both US and European standards.

![Figure 2: Wood Pellets](image)

Energy content is critical to many end users. For example, a high calorific value can lead to higher combustion temperatures and potentially damage furnaces. Pellets for export need to be sampled and tested to ensure conformance to standards.

Although details of the production process vary between companies, pellet production is generally applied for the processing of material which is not suitable to be made into wood chips. Typically the pellet production process consists of the following steps:

1. **Milling** - Raw material is reduced to a particle size of about 3mm and heavy woody elements are removed.
2. **Conditioning** - Material is dried to the right moisture content and temperature.
3. **Pressing** - The woody material is fed into the pellet press. Pellets are formed by compressing the wood in a dye, as shown in Figure 3, to achieve compaction. The shape/design of the dye used for the press, depends on the feedstock used.
4. **Cooling** - The wood pellets need to be cooled after leaving the press. Cooling the pellets ensures they harden, making them more robust during storage and handling.

5. **Screening** - Pellets are passed over a vibratory screen to separate fines.

6. **Storage** – Pellets need to be kept dry and can only be stored for a limited time.

**PRODUCTS AND MARKETS**

Wood pellets are a renewable and GHG neutral fuel alternative for old coal fired heaters and boilers as well as being able to be used in a range of modern combustion systems. As a fuel, pellets are comparable with coal in terms of energy content, and offer potential reductions in NOx and SOx emissions with usually less ash.

Pellets have benefits over wood chips and other types of wood fuel in terms of their consistency, moisture content and energy density and as such they are easier to ignite and handle. However they are typically more expensive to produce and excessive handling causes them to degrade and become more dusty.

In several European countries, wood pellets have proved to be a very popular alternative to fossil fuel based domestic, district and industrial heating systems and in small to large scale Combined Heat and Power Plants. The demand is driven by EU and regional incentive schemes making pellets competitive with fossil fuels. There is a general shortage of pellets in Europe and so pellets can attract premium prices. Market prices for pellets have been stated to be in the range of $100 to $350 per tonne delivered for bulk quantities. Retail prices at June 2006 in several European countries are shown in Table 5.

a. Assuming 19GJ/tonne
b. Assuming 1.00 AUD = 0.60 EUR
As a consequence of the shortage in Europe, pellets are currently imported from the east coast of North America into Europe, with a resulting net flow of pellets from the west coast supplying the east coast. There is also a net shortage of pellets in the US. Export of pellets from Australia to a number of overseas markets may be viable if economic shipping rates can be established. The export of bulk quantities of pellets from Australia is not a regular activity and the optimal approach would need to be developed. Considerations would include appropriate quantity and regularity, type of vessel (e.g., bulk carriers used for wood chips), fire suppression, loading and unloading mode and rates, etc. Many factors will impact shipping cost and consequently, economic viability.
CAPITAL AND OPERATING COST

Prices which have been provided by some pellet manufacturing equipment suppliers are listed in Table 6. Equipment prices vary significantly, mainly due to country of manufacture. Of course, a careful comparison of equipment specifications from each supplier is advisable prior to making any procurement decision.

c. Mills A, B and C represent generic sawmills of large, medium and small capacity respectively, and are defined in section 5.3
d. Prices are for an operational mill
e. $1 million for main machinery (pellet press) and $1 million for installation, buildings, steel, electrical and dryer
f. $30 million for main machinery (pellet press) and $5 million for installation, buildings, steel, electrical and dryer
g. There are 6off 3.5 tonnes per hour presses each requiring 240kW
h. Energy usage by electrical motors only – does not include thermal energy for drying if required. Energy for drying is discussed in section 3.2.
It is important to note that due to the extreme pressure used in a pelletising system (1.7GPa) wear parts such as dies need replacing regularly. This can represent a significant operating cost, depending on the type of wood being processed.

It is possible to make use of third party equipment, whereby pelletising plant is owned and operated by an equipment supplier and sited ideally at or adjacent to the sawmill. Sawmill residue in this case would earn a per tonne revenue, depending on the type of residue. Agreements would need to be established in relation to supply quantity and quality, energy requirements and permits, but potentially allow sawmill operators to avoid having to develop operational expertise in pelletising as well as removing sales and marketing issues.

The use of mobile pelletising plant may allow expertise to be sub-contracted or shared between nearby sawmills or other compatible biomass producers. Mobile plant is available from some suppliers, while others believe it is not a practically feasible option due to the high pressures involved.
3.3.2 Wood Briquettes or Synthetic Logs

TECHNOLOGY DESCRIPTION

Wood briquettes are made by compacting loose wood waste into a dense material through the application of high temperatures of approximately 300 to 350°C and moderate pressure. Sawdust, wood chips and bark are suitable for making briquettes, although sawdust is the preferred raw material. Briquettes can also be carbonized to create charcoal of very high quality (charcoal briquettes discussed in section 3.3.3).\(^\text{19}\)

PRODUCTS

Wood briquettes, shown in Figure 6, are similar to wood pellets but are physically larger. Briquettes vary in diameter from around 50 to 100mm and are usually 60 to 150mm long. They are generally burnt as a cleaner and more consistent alternative to firewood logs, offering a higher energy density and steady combustion.\(^\text{12}\) Wood briquettes can be used in stoves, furnaces and solid fuel burning equipment. However, in the fuel industry, briquettes have to compete with other fuels, such as wood and agricultural residues, kerosene and diesel, which are often cheaper, hence they are not high sellers in Australia at this stage.\(^\text{20}\)

![Figure 6: Wood Briquettes](image)

CAPITAL AND OPERATING COST

Prices for a briquetting plant/equipment have been provided by a couple of companies and these are shown in Table 7.

TECHNOLOGY STATUS

Wood briquettes are relatively common in colder countries for use in log wood fires. However in Australia with the low cost of gas heating they are not as frequently used. The best market for wood briquettes is seen to be as a heating source for residential use in small local communities.

There are no foreseeable technological developments for this product.

3.3.3 Charcoal Briquettes

TECHNOLOGY DESCRIPTION

Charcoal briquettes, shown in Figure 7 can be made from two different methods; turning the wood wastes into charcoal dust then making briquettes from the dust or carbonizing wood briquettes to charcoal briquettes.

![Figure 7: Charcoal Briquettes](image_url)
To produce charcoal briquettes from wood briquettes, the wood briquettes are made as per usual, they are then put into a carbonizing machine and pyrolysed.

The charcoal dust used to create charcoal briquettes is made from saw mill waste which has been screened and cut to a uniform size before being treated in an oxygen controlled vessel at temperatures of 315 to 980°C. The resulting char is mixed with other ingredients, such as a binder like starch, before it is moulded to the required briquette shape, dried and packaged. There are alternative methods which may be used but each of them follows this same basic principle.

PRODUCTS

Charcoal briquettes are a convenient source of burning fuel which tends to burn longer and more consistently than lump charcoal, but not quite as hot. Some briquettes contain ingredients in addition to charcoal to improve aesthetics of the product during combustion; consequently they can result in a larger amount of ash.

The majority of charcoal briquettes produced in Australia are made from coal char rather than wood due to the abundance and low cost of coal. There is only a small local market for wood char briquettes and they are generally considered to be uneconomical.

CAPITAL AND OPERATING COST

Prices have only been found for carbonising wood briquettes and not producing briquettes from char dust. The briquetting equipment listed in Table 7 is needed in order to produce charcoal briquettes. The prices of the carbonising equipment are shown in Table 8.

a. Assuming 1.00 AUD = 0.80 USD

Charcoal for use in barbecues is sold in Western Europe at a wholesale price of EUR 280 to 300 per tonne and bagged charcoal is sold in Moscow wholesale for around EUR 300 per tonne. No wholesale prices have been found for selling charcoal briquettes in Australia; however they are sold in service stations in metropolitan Melbourne for a retail price of $8 for a 10kg bag.

TECHNOLOGY STATUS

Around 4 to 6 million tonnes of firewood is burned in Australia per year and less than 50,000 tonnes of that is bagged wood. It is expected that this is not only because of price but also because people enjoy watching the unpredictability of the flames which are produced from wood. It is for this reason that it appears that charcoal briquettes would be unsuitable for a domestic fireplace market.

Charcoal briquettes are not commonly made in Australia because they are not economical. However, several Asian companies who manufacture the machinery used to make charcoal briquettes have been found.
3.4 Direct Combustion

Direct combustion of woody biomass yields net energy in the form of radiation, in the visible and infrared range of the spectrum, and sensible heat within the combustion products, predominantly in the flue gas stream. Combustion chambers are designed to facilitate efficient burning and to focus the evolved heat to where it is needed. Combustion chambers vary in design depending on the quantity and characteristics of the fuel and the way in which the heat will be used.

3.4.1 Theory

Combustion or burning of wood involves a complex series of chemical reactions, as outlined below.

3.4.1.1 Stage one - Drying and torrefaction

The first stage of combustion of wood is the heating and evaporation stage. The temperature of the wood surface approaches 100°C and the water in the wood evaporates. As long as water remains in the wood, the evaporation process maintains the temperature at 100°C. Moisture must be driven off before combustion can begin, so wood with high moisture content is hard to ignite. As the wood surface temperature rises beyond 100°C to about 230°C, torrefaction begins evolving gases such as carbon dioxide, carbon monoxide along with acetic and formic acids. The initial drying can take place either in the furnace (assisted by using hot combustion air) or in an external dryer.

3.4.1.2 Stage two combustion - Volatilisation

After moisture is driven from the wood and the temperature of the wood rises above about 280°C, the second stage of combustion takes place. This is the heat-producing stage. It occurs at two different temperature levels: primary and secondary combustion.

The process by which gases are released from the wood and burned is called primary combustion. Primary combustion begins at about 280°C, continues toward 500°C and results in the release of a large amount of energy. During this stage large amounts of unburned combustible gases, including methane and methanol as well as more acid, water vapour and carbon dioxides are produced. These gases contain up to 60% of the potential heat in the wood and their combustion is important to achieve high overall combustion efficiency. These gases are not burned near the wood because of a lack of oxygen.

The conditions needed to burn secondary gases are sufficient oxygen and temperatures of at least 600°C. The air supply is critical. Too little air will not support combustion and too much will cool the temperature to a point where combustion cannot occur. Air contains approximately 80% nitrogen, an inert gas, and when introduced into the combustion chamber it will be below the 600°C needed to sustain secondary combustion. The more air that mixes with the secondary gases, the greater the quantity of heat absorbed by the nitrogen, resulting in a lower the temperature of the secondary gas-air mixture.

3.4.1.3 Stage three combustion – Charcoal burn

After the gases are evolved from the wood, what remains is a char which is basically carbon. Carbon burns over a long time with a low rate of heat output and is reduced to ash to complete the combustion process.
3.4.2 Combustion in Practice

3.4.2.1 Approaches

The common method of combusting solid fuel such as biomass is to burn it on a grate with excess (greater than stoichiometric) air to ensure complete combustion as described above. A more recent process (at least in power production) incorporates an intermediate step - the gasification of the fuel. In this case the fuel is supplied with little to no air and the material is pyrolysed then gasified (often in the presence of steam) to produce a "syngas" (mainly CO, methane and H₂). The syngas can be combusted in a second stage, known as staged combustion, where the evolved heat is then usually directed into a boiler to produce steam. Alternatively, the syngas can be collected and stored for later use or burnt in an internal combustion engine or gas turbine. This technology is discussed further in section 3.5.

3.4.2.2 Staged Combustion

In staged combustion, the syngas is immediately mixed with air in a second chamber where it burns completely, the gas temperature rises and the heat is used usually in a boiler. Separating the stages of combustion provides a number of benefits, including:

- Improved control allowing oxygen levels to be optimised for each stage
- Pre-combustion (or gasification) can be performed at lower temperatures, reducing the driving force for a variety of ash related problems such as clinkering
- Gaseous phase combustion can be better controlled to ensure complete combustion and, by controlling the residence time at the desired temperature, reduce emissions of harmful halogenated organic compounds such as dioxins and furans

3.4.3 Biomass Furnace technologies

Modern furnace types basically fall into four categories: pile burners, stoker grate, suspension and fluidised bed. The advantages and disadvantages of each are outlined below in a qualitative sense. As mentioned in the section above combustion can be carried out by either 'conventional' means or by staged combustion or gasification. Apart from suspension burners, the other types of furnaces can be designed and used for any of the forms of combustion.

3.4.3.1 Pile Burners

In pile burners the biomass is dumped into piles in a furnace and burned with the help of combustion air coming from under and above the grate. Advantages of this technology are the fuel flexibility and the simple design. Whilst the burner/boiler is simple the disadvantages are the generally low combustion efficiency due to poor combustion control and the need to manually remove ash. This manual operation means that the pile type furnaces are not often used in commercial plant unless the ash content is very low.

3.4.3.2 Stoker Fired

Within the group of stoker fired boilers, there are three major types of grate namely stationary sloping grate, travelling grate and vibrating grate. The aim in each case is to automatically remove ash whilst helping to ensure complete combustion of the biomass. Common to these types is a fuel feeding system which puts a layer of fuel on the grate that is relatively small and more evenly distributed than in the case of pile burners. In a stationary sloping grate boiler the grate does not move, but the fuel burns as

Figure 8: A rotating grate furnace (a type of vibrating grate with an incline).
it slides down the slope. The disadvantages of this type of boiler are the difficulty in controlling the combustion process and the risk of avalanching of the fuel.

3.4.3.3 Travelling Grate

In a travelling grate boiler the fuel is fed on one side of the grate and has to be burned by the time the grate has transported it to the ash dumping site of the furnace. Combustion control is improved over a stationary (or fixed grate). As there is only a small layer of fuel on the grate, carbon burnout efficiency is also better in comparison with the stationary sloping grate boiler. In a vibrating grate boiler the fuel is fed evenly onto the whole grate. The grate has a shaking movement which spreads the fuel evenly. This type of grate has less moving parts than a travelling grate and therefore typically has lower maintenance requirements. Carbon burnout efficiency is further improved and in the case of water cooled grates it is possible to increase the amount of over-fire air, which has the advantage of less thermal NO\textsubscript{x} creation.

![Figure 9: A travelling grate type furnace.](image)

3.4.3.4 Suspension Firing

In suspension fired boilers the fuel is fired as small particles which combust as they are fed into the boiler. This system can be compared with the pulverised coal firing technology and as such requires fine friable fuel. Preparation of the fuel to a suitable state often involves intensive pre-treatment. The main advantage of suspension firing is high combustion efficiency.

3.4.3.5 Fluidised Bed

In fluidised bed systems, combustion air fed from below the furnace chamber through a mass of sand at a high speed so that the fuel becomes a seething mass of particles and bubbles. A general feature of fluidised bed systems is that they are flexible in the kind of fuel that can be fired, which makes them quite suitable for co-firing different kind of fuels. Carbon burnout efficiency is very high in fluidised bed systems.

Another important advantage is the possibility of controlling NO\textsubscript{x} creation by controlling combustion temperatures and to minimize SO\textsubscript{x} creation in the case of fossil fuel co-firing. A disadvantage of fluidised bed systems is the high demand for air to fluidise the bed. This requires large fans adding

![Figure 10: Bubbling Fluidised Bed](image)
There are two types of fluidised bed boilers, a bubbling fluidised bed (BFB) and a circulating fluidised bed (CFB). The selection of type of fluidised bed boiler depends on the fuel type, steam condition, etc. An advantage of bubbling fluidised beds over circulating fluidised beds is their lower capital requirement at modest scales (smaller than 60 MWth).

3.4.3.6 Bubbling Fluidised Bed (BFB)
In a BFB, materials in the furnace are fluidised by supplying fluidising air (combustion air) from the furnace bottom. Fuels are fed into the furnace whose temperature is kept within an optimum range for combustion or gasification. BFBs have a lower height of fluidised bed sand than CFBs and can burn up to 75% w.b. moisture content fuels although they are generally designed to handle 65%. BFBs are a square design and cannot easily be scaled up in size. As a result they have traditionally been used for smaller to moderate scales.

3.4.3.7 Circulating Fluidised Bed (CFB)
Due to the higher superficial velocity found in a CFB most of the particles leave from the furnace. These particles are collected by a cyclone located at the furnace exit, and then returned to the furnace for further combustion. CFB systems have better carbon burnout efficiencies and absorb acid gases more easily. The bed material, usually sand, needs to be cleaned regularly of ash and other non combustibles and this is done automatically in a circulating fluidised bed. CFBs would be used with biomass containing high chloride levels, as would occur in agricultural residues. CFBs have very low NOx emissions; however they are limited to 60 to 63% w.b. moisture content.

3.4.4 Heat and steam
The combustion of sawmill residues for useful heat is an obvious and in many cases prudent exploit. To make use of the evolved heat, it is commonly transferred to a heat transfer medium in a heat exchanger or a boiler. Saturated or superheated steam is a relatively inexpensive and efficient heat transfer medium and is widely used for process and space heating. Steam is also widely used for electricity production, which is discussed in section 3.4.5, and in co-generation, which is discussed in section 3.4.6.

Boiler types vary depending on the scale of the system and the pressures or temperatures required. There are two basic types of boiler - fire tube and water tube. Water tube boilers are more often favoured when high pressure steam is required, for example to drive a turbine. Water tube boilers are commonly either D-type or tower type and are used almost exclusively for steam pressures above 10 bar (g) \(^{27}\), especially to drive steam turbines. At lower pressures, fire-tube boilers offer relative simplicity and lower cost.

The thermal efficiency of a steam plant depends strongly upon the boiler pressure; the higher the boiler pressure, the higher the efficiency. Also, as the boiler pressure rises, the flow rate of the steam needed to produce a given power output falls. Conversely, lower pressures mean that more steam is needed and hence more fuel has to be used. On the down side, increasing boiler pressure means higher temperatures and necessitates the use of higher quality materials and construction techniques thus increasing system costs.

The amount of heat energy that can be extracted from wood is dependent on the type of wood residue, but more significantly on its moisture content. Table 9 shows the effect of moisture content on its recoverable energy. Compared with most fossil fuels, even bone dry wood has a relatively low heating value at typically 19 to 21MJ per kg. This value decreases...
significantly as moisture content increases. Green hardwood eucalypt typically has a moisture content of around 30% w.b., while green softwood pine typically has moisture content around 50% w.b.

Table 9: Heating values (wet basis) of a typical wood at various moisture contents compared with fossil fuels.

a. Eucalypt hardwood  
b. Calculated, wet basis

The successful commercial operation of the plant is heavily dependent on the total amount, rate of delivery and quality of the fuel. These factors influence the technologies employed in the furnace, which can have a large impact on the capital costs (CAPEX) and operating costs (OPEX). Clearly, the amount of fuel available largely determines the upper limit on the size of the plant. The fuel size is another important factor, since the cost of purchasing hogging or chipping equipment for size reduction is significant and the operating costs are very high, especially the power consumption.

The inorganic content of some types of biomass fuel presents specific difficulties compared with fossil fuels. Some types of biomass used contain significant amounts of chlorine, sulphur and potassium. The salts, KCl and K₂SO₄, are quite volatile, and the release of these components may lead to heavy deposition on heat transfer surfaces, resulting in reduced heat transfer and enhanced corrosion rates. Severe deposits may interfere with operation and cause unscheduled shut downs. The release of alkali metals, chlorine and sulphur to the gas-phase may also lead to generation of significant amounts of aerosols (sub-micron particles) along with relatively high emissions of HCl and SO₂.

The type of furnace for burning biomass would generally be either a variety of stoker grate or fluidised bed. In grate-fired furnaces, deposition and corrosion problems are the major concern when using dirty or high alkali fuels. Fluidised bed combustors are frequently used in these cases with circulating fluidised beds being the preferred choice in larger units. Here, silica and other inorganics in the biomass may cause agglomeration of the bed material requiring specialised agglomerate removal systems.

Fuel consistency is also a factor, particularly with regard to homogeneity and moisture content. Variations in fuel size and feed rate will influence the type of furnace selected, with some types more able to adapt to load and fuel burning characteristics. Moisture content is particularly crucial in furnace selection. In general terms, for moisture contents less than say 55% grate boilers can be used, although at this level some pre-drying is probably required. At moisture contents from 55 to 65% w.b. fluidised bed boilers are used.
In modern furnaces a high combustion quality is achievable, yielding efficient heat recovery and low emission levels. Combustion quality mainly depends on the combustion chamber temperature, turbulence of the burning gases, residence time and the amount of excess oxygen. These parameters are governed by a series of technical variables such as:

- combustion technology (for example, combustion chamber design, process control technology)
- settings of the combustion (for example, primary and secondary air ratio, distribution of the air nozzles)
- load condition (full- or part-load)
- fuel characteristics (shape, size distribution, moisture content, ash content, ash melting behaviour)

The air borne emissions from a modern biomass furnace are a vast improvement from domestic heaters or open air uncontrolled combustion. However, even in modern furnaces combustion will need to be carefully controlled in order to meet EPA standards. It is likely that a bag house filter would be required to keep particulate emissions below the legal level, depending on location.

### 3.4.5  Electricity

As indicated in Figure 1 the combustion of wood can be employed to generate electricity either through direct combustion to produce steam then passing the steam through a steam turbine or steam engine to drive a generator, or first gasifying the wood and combusting the gas in a gas turbine or internal combustion engine to drive a generator. The steam route requires direct combustion and boiler technologies as outlined above. The gasification route requires pyrolysis and gas clean-up technologies as outlined in section 3.5.1.

#### 3.4.5.1  Steam turbine system

Steam turbine systems are an established, widely available and robust technology but are generally only economically feasible on biomass fuels above 5MW<sub>e</sub> and are marginal below 10MW<sub>e</sub>. This corresponds roughly to 50,000 to 100,000 tonnes per year of dry wood waste. The rule of thumb presently used by the industry for these types of biomass fuelled generation systems is $2 to 3 million per MW<sub>e</sub> for new equipment. For a mature power generation technology, the industry rule of thumb for maintenance costs is typically 1.5% of capital investment per year. This can rise to 5-10% for less mature technologies. Indicative total operating costs for a 10MW<sub>e</sub> plant running 8000hrs per year are laid out in Table 10.

**Table 10**: Indicative breakdown of direct operating costs for a 10MW<sub>e</sub> steam turbine power generation system fuelled by sawmill residues and operating 24hrs/day with dedicated staff.

</table>
Steam turbines normally require superheated steam, which is steam that is heated above its boiling point at a given pressure, to ensure the steam is free of droplets that would erode the turbine blades. Therefore, a boiler driving a steam turbine requires a superheater. Typical superheated boiler pressures are usually either 46 bar or 64 bar and the steam is superheated to temperatures around 450°C (these pressures and temperatures are largely driven by limitations in the material grades used). Increased efficiency and fuel economy is achieved through the use of an economiser, which is a feed-water heater where the heat from flue gases is recovered to raise the temperature of feed-water supplied to the boiler.

A plant using steam boilers needs a source of high quality water for initial filling and then for continuous make up. All steam plants need make up water for both the boiler, where water is lost through leaks, during blow down and due to bleed off for process use, and for the cooling tower, where water is lost through evaporation. A typical boiler plant may need around 10% make up water, that is 10% of the boiler capacity needs to be made available for make up. Additional make up water is also usually required for the cooling tower, although this water can be of a lower purity than that used in the boiler. For a 30MW boiler operating at 46 bar water is evaporated at around 50 tonnes per hour. This plant may need up to 5 tonnes per hour of boiler make up water. The water will have to be of high quality and the use of a purification plant such as Reverse Osmosis may be needed along with chemical treatment.

A condensing turbine provides the most efficient cycle, whereby steam passes directly from the turbine into a condenser, operating at sub-atmospheric pressure, enabling the maximum amount of energy to be extracted in the turbine. Condensers are used to condense the steam that exits the turbine back into a liquid so that it is able to be pumped. Typically condensers use re-circulated water that is cooled either in a cooling tower or via a cooling pond.

Cooling towers are typically either wet or dry. As the name implies wet cooling towers need a source of water that is evaporated. Dry cooling towers, using forced convection of air through a heat exchanger, are typically more expensive and constitute a larger parasitic load as electricity is required to drive the fans.

The Organic Rankine Cycle (ORC) is similar to a conventional steam turbine cycle, except that the fluid which drives the turbine is an organic fluid with high molecular mass. The selected working fluids efficiently exploit low temperature heat sources to produce electricity in a wide range of power outputs (2kWe up to 3 MW), For a CHP system, high temperature thermal oil is used to transport the heat and a regenerator is added, to further improve the cycle performance. One of the main advantages of the ORC is that it offers improved efficiency to steam systems with net electrical and thermal efficiencies of 18% and 80% respectively.

3.4.5.2 Steam engine

Steam engines, like those shown in Figure 12, are a flexible electricity generation option, most suitable at scales less than a few MW. Steam engines, being supplied with steam from an external combustion plant, can burn a wider variety of fuel cleanly and efficiently compared to internal combustion engines.
In a reciprocating steam engine the steam is expanded in cylinders to provide the motive force. The steam, in expanding, causes the quality (dryness fraction) to decrease and potentially form droplets of water. These would lead to corrosion in the cylinder; therefore, it is important to ensure that the steam entering the cylinders is very dry (no entrained water droplets) or ideally slightly superheated.

Figure 13 shows a relatively linear power output versus steam flow rate relationship from around 25 to 100% of the engine capacity; and that the specific steam consumption (steam consumed per unit of power generated) is relatively flat in this range. In other words, the efficiency of the engine remains roughly constant whether it is running at full load or turned down to a quarter of a load. In contrast, steam turbine efficiency decreases significantly as steam flow rate is reduced below its design value. The good turn down performance of the steam engine is particularly applicable when steam supply is widely variable, in contrast to steam turbines which have very poor efficiencies at high turndown.

Steam engines are commonly used as part of a co-generation system as described in section 3.4.6 below. In co-generation applications, steam engines are normally operated in back pressure mode where the exhaust heat is also used (for example in drying kilns). In this operation mode they have a better electrical efficiency than steam turbines, combined with their very good part load efficiency.
If the focus is solely on electricity production and the load is quite constant, a steam turbine would normally achieve a higher electrical efficiency because a turbine can expand the steam more fully into a vacuum.

Presently, Spilling, who are based in Europe, USA and Asia, are the only notable manufacturer of reasonably sized reciprocating engines. 34

Figure 14: Spilling Steam Engine used by Big River Timbers

A Spilling steam engine used by Big River Timbers in New South Wales is shown in Figure 14. This mill has a 2-cylinder engine with a quite high inlet pressure of 3400kPa, expanding 5.5 tonnes of steam per hour to approximately 100kPa (g). The nominal electrical output is 428 kW. Other examples of applications of Spilling engines are shown in Table 11.

a. The maximum steam flow rate through the biggest Spilling steam engine, a 6-cylinder-type, is for the inlet and outlet pressures given in Appendix I. In this case it would need to be decided either to limit it to that size or to use two 4-cylinder-engines or one 2-cylinder-engine and one 6-cylinder-engine or to use a steam turbine. With two engines (2 x 4-cylinder or 1 x 6-cylinder and 1 x 2cylinder) the total electrical output with 18 tonnes per hour of steam flow would be approximately 1520kW and the total thermal output approximately 10,350kW.

b. Assuming 1.0 AUD = 0.6 EURO

Note: These prices do not include engineering, documentation, packing, transport and commissioning.

Additional parts which are sometimes also delivered by Spilling are compensators - to be installed in the pipes to and from the steam engine to avoid a transfer of vibrations, a pressure reducing station - to be installed parallel to the steam engine, a condensate tank and condensate pumps and a heating condenser.

The electrical efficiency of the steam engines described in Table 12 is approximately 12%. There is also a thermal output (in this case at 50kPa and 110°C) which is approximately 6 to 7 times as high as the electrical output.
3.4.5.3 Gas turbine

Gas turbines can be fuelled by sawmill residues by first gasifying the wood (refer to section 3.5.1) and cleaning the pyrolysis gas or syngas. The syngas is combusted within the gas turbine engine and the resulting gas expansion is used to rotate the turbine and drive a generator. At larger scales and with fossil fuels, gas turbines are often coupled with a heat recovery steam turbine system, whereby heat is recovered from the high temperature gas turbine exhaust and used to produce steam, which is used to drive a steam turbine and generator. Known as Integrated Gasification Combined Cycle (IGCC), these systems have been extensively trialled but have not been found to be commercially viable with wood fuels, primarily due to size constraints. However, IGCC systems offer the potential to achieve higher overall electrical efficiencies of 22 to 37% compared with 15 to 18% typical for steam turbine based biomass fuelled generation systems.

While conventional gas turbine sizes range from 500 kW to 350 MW, micro-turbines are in development with capacities from 30 to 400 kW, however, they are targeted at usage with fossil fuels. Like larger gas turbines, micro-turbines can be used in power-only generation or in combined heat and power (CHP) systems, which are explained in more detail in section 3.4.6.

Micro-turbines generally turn at a higher rotational speed than larger gas turbines to achieve the same blade tip velocity with a smaller diameter. Speeds are generally 60,000 to 100,000rpm depending on the specific turbine design characteristics.

A schematic of a micro-turbine based CHP system running on natural gas is shown in Figure 15. In a recuperative micro-turbine, atmospheric air is compressed, heated and mixed with fuel in the combustor. Hot combustion gases expand in the turbine causing rotation. The expansion turbine turns the compressor and, in single-shaft models, turns the generator as well. Using fossil fuels, micro-turbines can achieve electrical efficiencies of 25 to 33%, although efficiencies generally decrease at elevated ambient temperatures.

![Figure 15: Schematic of a micro-turbine based CHP system](image)

Micro-turbines running on syngas would require a fuel gas booster compressor to ensure that fuel pressure is adequate for the gas turbine flow control and combustion systems. Booster compressors can add from $50 to $100 per kW to a micro-turbine CHP system's total cost. As well as adding to capital cost, booster compressors lower net power and efficiency so
operating cost is slightly higher. Typically, the fuel gas booster requires about 5% of the micro-turbine output.

Micro-turbine exhaust can also be used to produce heat at high temperatures that can be used directly or by means of a heat exchanger in drying or pre-heating processes. Exhaust can also be used for preheated combustion air.

Micro-turbines are currently operating on biogas from landfill and MSW operations. However, no commercial micro-turbine systems have been found that operate on pyrolysis gas.

A project was carried out by CSIRO and a Melbourne based engineering firm, J C Smale, to demonstrate electricity generation from biomass via gasification and a micro-turbine. The project used a Capstone micro-turbine and was aimed at the 30 to 200kW size range. The project successfully demonstrated wood waste gasification and electricity generation via the micro-turbine, although only in short runs. Sawmill partners are currently being sought to provide a site for and partially fund a full scale Beta test unit, which is intended to continuously generate power.

3.4.5.4 Internal combustion engine

Like gas turbines, reciprocating Internal Combustion (IC) engines can also be fuelled by sawmill residues by first gasifying the wood and cleaning the syngas (refer to section 3.5.1). IC engines are generally suited to small scale electricity generation of up to a couple of MW_{e}.

There are a number of developers and suppliers of syngas fuelled IC engines, with considerable experience residing in Europe and India. A demonstration plant in Güssing, Austria has been operated by Repotec since 2002 and currently reaches 7000 operational hours per year. The plant consumes approximately 1.8 tonnes of wood per hour (woodchips or pellets, but not sawdust) and produces 2MW electricity and 4.5MW of district heat. The system has an electrical efficiency of around 12%. Repotec are marketing the technology in the size range 1.5 to 6MW_{e}, however this is mainly in Europe.

Ankur Scientific Energy Technologies is an Indian based supplier of biomass gasification systems for heat and power applications in the size range 5kW_{e} to 500kW_{e}. They have around 700 gasification systems installed around the world, including at 40kW_{e} dual fuel power generation system installed at Forestry Tasmania. Sold through Alternative Energy Solutions (AES) in Australia and New Zealand, their gasification technology typically uses partial oxidation fed with air yielding a producer gas with a relatively low heating value (typically 4MJ/m^{3}). Electrical conversion efficiency are claimed to vary from 16 to 24%.^37

Carbona, based in Finland, has a number of larger scale biomass gasification power and cogeneration systems around the world. Carbona have developed fixed bed gasification systems in the range 1 to 15MW_{e} and fluidised bed gasification systems up to 200MW_{e}.^38
A small scale integrated gasification and IC engine product is available in the US, shown in Figure 16. The BioMax system comes in 5 to 50kW_{e} modules and is installed in a number of sites throughout North America. BioMax is manufactured and marketed by Community Power Corporation (CPC), however at this stage only into North America. 39

As with all international technologies being introduced into Australia, it would need to be ensured that this equipment is compliant with Australian standard. It would also need to be tested with Australian woods to confirm that they are suitable.

3.4.5.5 Generators

Generators are generally supplied as a matched unit together with a turbine or other engine. Some generators or alternators are integrated with turbines or engines and offer a better performance and efficiency than discretely joined systems.

GenSets, the actual electrical generation and conditioning components of a power generation system, may comprise generators or alternators, inverters, transformers and a control system. If power is to be sold to externally via the grid, then a grid interconnect system will also be required. Grid interconnection is not trivial and procurement agreements with utilities will probably include provisions for continuity and uniformity of output.

To gain assistance in connecting to the grid for a relatively large scale grid addition, that is greater than approximately 30MW_{e}, the National Electricity Market Management Company (NEMMCO) should be contacted. Otherwise the local electricity distribution network or the dominant electricity retailer for the area should be contacted.

3.4.5.6 Fuel cells

Fuel cells are an entirely different approach to the production of electricity. Fuel cell stacks are silent, have no moving parts and have potential fuel efficiencies far beyond the most advanced reciprocating engine or turbine power generation systems. Fuel cells produce power electrochemically when hydrogen is delivered to one side of the cell (anode) and oxygen is delivered to the other side (cathode). Charged atoms or ions of either hydrogen or oxygen, depending on the fuel cell type, pass across a gas impervious membrane to react on the other side. The flow of these charged ions is a direct electric current.

Each cell produces a high current density at low voltage - usually less than 1V. To increase voltage, individual cells are connected in series to form a fuel cell stack with common fuel and
air gas streams. The exhaust streams contain hot gases, from which useful heat can be recovered to form a combined heat and power system. The basic elements of a fuel cell CHP system is shown in Figure 17.

![Figure 17: Schematic operation of a fuel cell system.](image)

There are several different liquid and solid membranes that support these electrochemical reactions - phosphoric acid (PAFC), molten carbonate (MCFC), solid oxide (SOFC) and proton exchange membrane (PEM) are the most common systems. Each of these distinct fuel cell technologies operates under different conditions and temperatures, each with its own performance characteristics.

Direct electrochemical reactions are generally more efficient than using fuel to drive a heat engine to produce electricity. Fuel cell efficiencies range from 35 to 40% for the PAFC to upwards of 60% for the higher temperature SOFC systems. If heat is recovered in a combined heat and power system then overall efficiency can be upwards of 80%. The hydrogen fuel that the fuel cells burns can come from reformed methane or liquid fuels.

Like a battery, fuel cells produce direct current (DC) that must be passed through an inverter to get 50 Hz AC.

PAFC and PEM fuel cells are the most widely deployed fuel cells with some commercial systems available. SOFC and MCFC technologies are largely in field test or demonstration stages.

As with most new technologies, fuel cell systems have several disadvantages, such as product immaturity, over-engineered system complexities and unproven product durability and reliability. These translate into high capital cost, lack of support infrastructure and technical risk for early adopters. However, the many advantages of fuel cells are driving their development and they could well become a viable product in the future.

### 3.4.6 Co-Generation

Co-generation - also known as combined heat and power (CHP) - refers to the simultaneous production of useful heat and electricity. In a CHP plant, heat is usually produced in the form of steam and piped to where it is needed. The steam produced can provide a large amount of lower temperature energy for applications such as kiln drying.

The key to designing an efficient CHP plant is to balance the demand for process heat and electricity. The scale of the plant, required pressure (or temperature) and the demand over
time all influence the type of CHP technology used. By using a CHP plant, considerable overall energy savings can be obtained, thus it can be a very attractive alternative with short payback periods.

In a gasification based CHP system, it is relatively straight forward to extract heat by directly combusting the gas when and where required. In this case, there would be minimal gas clean-up required. Alternatively, the heat in the flue gases from a combustion chamber (or the exhaust from the cylinders of internal combustion engine) could be used. Heat exchangers are sometimes used to avoid problems associated with noxious fumes.

Where electricity is produced via steam, either using direct combustion or gasification then combustion, then the steam can be a useful external source of heat. This is common in Europe where steam is piped for community heating. Steam is also a useful heat product in wood drying, where humidity levels must be controlled. Extracting steam from a steam turbine circuit for heat presents some difficulties, depending on the quantity, temperature and pressure and regularity of steam demand.

A steam turbine CHP system will generally be used when there is a steady demand for heat or only low grade heat is required. Generation of steady high grade heat may be accomplished by extracting steam from the turbine casing or by using a back pressure turbine. If the steam is to be extracted from the turbine casing, the pressure of the steam depends on the point along the turbine at which steam is extracted, thus determining how much the steam has expanded. In these set-ups, the turbine and generator average output are somewhat below their rated capacity, resulting in low utilisation and low average efficiency. This is usually a waste of capital.

Alternatively, backpressure steam turbine systems function by regulating the exhaust from the turbine to yield steam at the desired pressure. In these turbines, condensing occurs during or after the downstream process that uses the heat. This type of system does not utilise the latter part of the steam expansion cycle and has correspondingly a lower electrical output. If the steam were not used, for example due to uneven demand for heat, this energy is lost. Steam accumulators can be used to even out demand and maintain the highest possible utilisation of the turbine and generator.

Reciprocating steam engines are generally superior when there is a widely varying steam supply, due to their flat efficiency curve as explained in section 3.4.5.2. However, steam engines are generally restricted to small scale systems, typically 10 to 2000kWs.

TECHNOLOGY STATUS

The use of biomass (wood) fired CHP plants at a commercial level is quite recent and indeed there is still plenty of product development happening around the world.

Scandinavian countries such as Finland, Sweden and Denmark, with little indigenous hydrocarbon based fuel, have been at the forefront in the development and use of biomass for CHP plants. Whilst other EU countries such as Germany and Italy are keen to adopt biomass power generation plants in part to use waste streams that are presently heading to land fill and also to reduce Greenhouse Gas Emissions. There are some significant financial incentives for the installation and operation of biomass energy plants in these countries.

The USA has a long history of using wood for heating and power generation and there are a large number of suppliers of plant and equipment. In New Zealand the use of biomass boilers is about 40 years old, whilst in Australia the sugar industry has been using bagasse as a fuel in their boilers for decades. In more recent times the development and use of biomass plants in Australia has had a chequered history.

Some international examples of small scale co-generation plants are listed in Table 13.

3.4.7 Co-Firing

Co-firing, the simultaneous combustion of dissimilar fuels in one furnace or boiler, is a highly promising technology for using wood residue fuels in large-scale kilns and utility boilers. Co-firing of biomass production wastes in stoker-fired boilers is not new and there are a variety of techniques which are available for industrial boilers. The combustion technology most commonly used in the steam boilers of the pulp and paper industry is the traveling grate in spreader-stoker boilers. These systems readily lend themselves to co-firing. It is common for pulp mill power boilers to be fired with combinations of wood waste, coal, pulp mill sludge, and other fossil fuels and wastes. Such firing maximizes responsiveness to changing load conditions while minimizing fuel costs.

Co-firing of biomass in large scale utility boilers (those used for power generation) enables the use of the larger capacities of such boilers, the higher main steam pressures (typically 16MPa to 24MPa) and the incorporation of reheat steam into the boilers, with corresponding efficiency and availability benefits compared with smaller scale industrial boilers.⁵¹ Co-firing of wood chips in other biomass fuelled systems such as cogeneration systems operated by
the sugar mills can be of particular benefit when the primary biomass source (bagasse) has seasonal availability. This approach has been developed at the Rocky Point Sugar Mill, where other waste-to-energy biomass fuels have been identified and trialed to enable the plant to operate year-round.

Co-firing is an effective means for Greenhouse Gas mitigation by using biomass to partially displace fossil fuel and simultaneously remove wood waste from being interred in landfills. Because biomass contains low concentrations of sulphur and nitrogen, co-firing also reduces SO$_2$ emissions and, in most cases, NO$_x$ emissions from coal power plants. Biomass co-firing also provides a low cost approach to increasing generation capacity for base load "green power" without major changes to existing equipment.

### 3.5 Pyrolysis and Gasification

Pyrolysis is the chemical decomposition of organic materials by heating in the absence of oxygen or any other reagents, except possibly steam, or by partially combusting in a limited oxygen supply. The decomposition products are a mixture of gas, condensable tars/oils and char residues. Depending on the conditions (heating rate, temperature, atmosphere, particle size etc.) the product distribution can be adjusted and optimized to suit the application. Gasification is a form pyrolysis that is generally carried out with the introduction of more air and sometimes steam and at higher temperatures, to optimise the production of gas. Typical pyrolysis conditions and product yields are shown below:

<table>
<thead>
<tr>
<th>Mode</th>
<th>Conditions</th>

<td>Pyrolysis/Carbonisation (300-550°C)</td>
<td>low temperature, very long residence time</td>
<td>30%</td>
<td>35%</td>
<td>35%</td>
</tr>
</tbody>
</table>

Depending on the process, some of the products are commonly combusted to provide the heat for pyrolysis.

#### 3.5.1 Gasification

The gas produced by gasification is commonly called synthesis gas or syngas, and is a mixture of carbon monoxide, hydrogen and methane, together with carbon dioxide and nitrogen. As mentioned above, the process generally produces a fraction of solid char and tar that will condense to liquids at ambient temperature. These are normally separated in a subsequent clean-up step (described below).

The ultimate composition of the syngas and its energy content will depend upon the specific wood variety and residue mix used and the operating conditions for conversion, significantly the approach used to supply heat. Most gasifier designs use oxygen as an oxidizing agent, either in air or in a concentrated form, partially combusting the wood and generating heat. In air-blown gasification, nitrogen in the air dilutes the syngas product, so that a low-energy producer gas results, containing perhaps 45 to 60% nitrogen, 10 to 20% hydrogen and 15 to 30% carbon monoxide. This low-energy syngas can be used where the heat content of the gas is not critical.
A medium-energy syngas can be produced by blowing concentrated or pure oxygen into the gasifier for partial combustion. This avoids nitrogen dilution in the syngas and increases the energy content. Alternatively, heat can be provided to the gasifier by an external source reducing dilutant gases to those entering with the fuel. The key differences between partial oxidation and indirect heating gasification are shown in Table 15.

</tbody>
</table>

Theoretically, a biomass gasifier is a fairly simple device consisting generally of a cylindrical container with internal space for reaction and ports for fuel inlet, gas inlet and gas exit. The cylinder can be made of masonry or metal. In practice, gasifiers have been designed in numerous configurations. Fixed bed gasifiers are most common and are best suited to small scale gasification. Fluidised bed gasifiers are also used widely, particularly at larger scales, being either Bubbling Fluidised Bed (BFB), Entrained Flow or Circulating Fluidised Bed (CFB) type. Various types of travelling grate beds have been used as well as molten salt reactors.

Fixed bed gasifiers are characterised by a stationary reaction zone that is normally supported on a grate. They are usually in up-draft (counter current) or down-draft (co-current) configuration, as illustrated in Figure 18, with down-draft generally producing a cleaner gas in terms of particulates and tars.

Figure 18: Fixed bed gasifiers in down-draft (left) and updraft (right) configurations

The core gasification vessel is usually part of an integrated system also comprising a fuel pre-treatment and feed system and a gas cleaning unit.
The evolved syngas may be burnt in either a gas engine or gas turbine, which are usually coupled to generators to produce electricity, as discussed in section 3.4.5. The syngas may also be used in a fuel cell with conversion directly to electricity, as discussed in section 3.4.5.6. Alternatively, the syngas may also be processed into liquid fuels using Fischer-Tropsch or other synthesis processes. Each application will demand a tailored gas specification, for example in terms of energy content, contaminant level, composition, temperature, etc.

3.5.1.1 Gas Cleanup and Conditioning

The product gases from the gasifier generally require treatment before they can be used for their final application - except for in a close-coupled gasifier-combustor system where there is no cleanup of the gases at all.

For gas turbine applications in a power system the gas has to be free of particulates, tars, sulfur and chlorine compounds and alkali metals to ensure the integrity of the hot section of the turbine. Particulate removal to protect the turbine blades from erosion requires filtration technology, while the removal of tars ensures an even and less luminous combustion process - to avoid radiant heat transfer problems at the turbine. Alkali metal removal is to avoid deposition and corrosion of the turbine blade materials and has to be carried out down to levels of potassium and sodium less than 1 ppm (part per million) to ensure long turbine blade and hot section lifetimes. The tolerance to alkali metals is a function of the temperature of operation of the turbine inlet section, at very high temperatures (greater than 1350°C) the level has to be about 25 ppb (parts per billion). The deposition and corrosion problems can also be addressed by means of turbine blade coatings. It is likely that both coating components and making them more rugged will be required as well as enhanced gas cleanup developments.

For internal combustion applications it is necessary to cool the gas to ensure that a sufficient charge of energy can be put into each cylinder – the lower temperature gas has a higher density and therefore higher volumetric energy density. Particular attention has to be given to both tar and particulate contents to ensure that the valves and cylinders are protected.

Fuel cell applications would require the gas to be mainly hydrogen without any significant sulphur or chloride contamination to protect the electrodes.

For synthesis operations such as methanol and hydrogen production removal of particulates and contaminants such as hydrogen sulphide is required to prevent poisoning of downstream catalysts.55

There are different processes to remove these unwanted components, the selection of which depends on the application. The following is a list of possible processes:

- Tar Removal
- Cyclone Separator for Dust
- Bag Filter
- COS Hydrolysis in Scrubber
- HCl scrubbing with NaOH or reaction in bag filter
- Tar condensation
- NH₃ + HCN, scrubbing with H₂SO₄ or Sulphinol D
- H₂S + COS, scrubber with COS hydrolysis or Sulphinol D, traces removed with ZnO filter
- S-Oxidation followed by desulphurization system with lime or limestone

In practice, the tars are normally broken down at high temperature before they pass through a filter to prevent contamination of the filter elements. This is usually carried out in a ‘tar cracker’ where high temperatures and a catalyst break down the tar into lighter fractions.
The processes that only separate contaminants present a further issue of disposal, which can become a significant cost and environmental problem, particularly if dirty or high ash input streams are used.

It is important to recognise that gas cleanup is a highly important step in rendering syngas suitable for the applications explored in this report. This operation is not easy to perform efficiently and consistently and represents a major challenge for most biomass gasification based technologies.

3.5.1.2 Fischer-Tropsch Process

A purified and high energy syngas may be put through the Fischer-Tropsch (F-T) process to synthesise liquid hydrocarbons. This process has been used for decades, most notably by Germany during the Second World War and by South Africa (SASOL) in the 1970s and 80s, to produce synthetic liquid fuels from coal or natural gas. In the F-T process, the carbon monoxide and hydrogen in the syngas are reacted in the presence of heat and a catalyst (typically iron and cobalt) to produce a liquid comprising of various hydrocarbon fractions. The various fractions may be separated by distillation or other separation processes into synthetic equivalents of automotive fuels. The F-T diesel can be created with a higher yield if first F-T wax is produced, followed by hydro-cracking (a process that employs elevated temperature and pressure essentially to crack carbon double bonds and rings). Heat is evolved during these synthesis processes and frequently used to dry the fuel, aid distillation and similar.

While F-T conversion of coal is well established, there are technical issues still being resolved in adapting this technology to biomass. During gasification, biomass reacts at a lower temperature than coal and has different ash characteristics, requiring a different reactor design.

In Germany, a pilot production facility is currently in operation for the production of F-T liquids from biomass.

The F-T Process is used by Zero Point Clean Tech in the production of ethanol via the multi-stage gasification process (refer to section 3.5.1.2). The syngas from the gasification is passed through an F-T reactor initially and then the refined finished ethanol is put through a final stage distillation process. As a consequence the economics start to make sense using multiple gasifier lines. Zero Point has investigated 20, 40 and 60 million litres per year configurations, each of which they believe makes commercial sense. These typically have 4, 8 and 10 gasifier lines. Zero Point has said that the system could scaled up to 80 to 100 million litres per year, however beyond which the multi-gasifier approach probably makes less sense economically.

3.5.1.3 Other Synthesis Processes

The conversion of syngas into a variety of other fuels is also possible and like F-T conversion, they “piggy-back” on available and established technologies. The development work involves controlling the gasification and clean-up stages, then adapting the synthesis processes to a different feed gas. Bio-fuels under development include:

- **Bio-SNG – Synthetic Natural Gas**: is produced from the syngas via a process called methanation, which uses a nickel based catalyst to produce a methane (CH₄) rich fuel stream. Compared to other synthesis fuels including F-T, a lower gasification temperature can be used prior to methanation – at lower temperatures some methane is produced in the syngas which subsequently helps control the methanation process by reducing the energy released from this highly exothermic reaction. The lower gasification temperatures can help reduce technical difficulties with biomass gasification. Bio-SNG can be used for transport fuel as well as stationary heat and power potentially using existing infrastructure. A technology demonstration plant of approximately 1MW capacity is under development by Repotec in Güssing, Austria using solid biomass fuels.
• **Bio-hydrogen** – Gasification employs a water gas shift reaction to increase the hydrogen yield and fully oxidise the carbon to carbon dioxide. Carbon dioxide is usually separated by pressure swing absorption and the hydrogen is then typically compressed. Hydrogen may be used as a fuel in internal combustion engines or fuel cells.

• **Bio-methanol** – Unlike F-T conversion, methanol synthesis preferably takes place in the liquid phase, which results in a higher yield. Bio-methanol can be used as a petrol substitute in spark ignition engines due to its high octane number, although like bio-ethanol, it has a lower energy density, lower vapour pressure and may be incompatible with certain engine materials (rubbers and plastics). It can alternatively be used in fuel cells being directly converted to electricity. Methanol must be treated with particular caution as it is poisonous and burns with an invisible flame.

• **Bio-DME (Di Methyl Ether)** – In the chemical industry, DME is usually produced from pure methanol via a process called catalytic dehydration, which chemically separates water from methanol. Often methanol and DME are produced together in one process. Bio-DME can be produced directly from synthesis gas, but this is still under development.

### 3.5.2 Carbonisation

The conversion of woody biomass into charcoal (char) is an ancient process which continues today. The early process was carried out by piling up wood, setting it alight and covering it with earth. Holes poked in the earth cover allowed air in to control the charring process. The char is produced by driving off the volatile compound in the wood leaving basically a carbon rich solid. This 'direct' method is still used today but in-direct heating is also used. In this case the wood is placed in a container which is heated externally, often by burning the volatile gases driven off the wood during charring. The first method is a batch process whilst the second method can be used in a continuous process.

The char produced is used as:

- A reductant in metallurgical processes
- An absorbent for odour and chemicals
- Fuel for cooking (BBQ)
- Fuel for heating (often in the form of briquettes)
- Soil improver (also a carbon sequestration material)

Generally all species of wood can be carbonised to produce useable charcoal. There is a variation in the ash content of different woods but this is generally not significant. Bark, however, has unacceptably high ash content and the structure of bark charcoal is too friable to be useful for most purposes. Therefore, where possible, bark should not be used or the amount of bark charred with the wood should be minimized. Softwoods generally produce a softer, more friable charcoal than hardwoods but they are a good raw material and can produce all types of charcoal. Eucalypt species produce good dense charcoal and are often the preferred species for the purpose.

The rate of carbonisation is closely related to wood size. Large wood pieces carbonise slowly since the transfer of heat to the interior of the wood is a relatively slow process. Whereas sawdust can be flash carbonised very rapidly but the powdered charcoal produced has a low market value. On the other hand, large diameter trunks of dense species may shatter when carbonised, making the charcoal more friable. Studies have shown that charcoal with
optimum properties for use as a reductant in the iron industry is produced with wood pieces measuring about 25 to 80 mm across the grain. Length along the grain has little influence.

A tonne of wet wood with a moisture content of say 25% w.b. clearly has 750kg of dry wood and this can be expected to produce approximately 200-250kg of char. The rest of the mass is volatilized. Thus the yield is approximately 20-25% (wet wood to char).

The cost of production is dependent upon the type of plant used, the process (batch versus continuous) and cost of the wood feed stock. Some cost estimates are shown in Table 16.

### Table 16: Approximate costs of charring.

*Note: These figures based upon a tonne of char do not include transport of the char to market and are based upon an exchange rate of A$1 = US$0.80*

In Australia it appears as though the largest producer of charcoal, albeit from coal feedstock, for commercial use is Simcoa Operations Pty Ltd who uses the charcoal in their own silicon manufacturing plant. Other than this use there does not appear to be a market in Australia for the sale of charcoal in commercial quantities.

Another type of char which is produced is called agri-char. Agri-char is made from biomass, usually by pyrolysis and often subsequent gasification (to further activate the char) and used as a soil enhancer. The carbon in the char can be viewed as a form a sequestration of CO₂ from the atmosphere into the soil thus reducing the CO₂ foot print. The char is a far more stable form of carbon than that in the original biomass and thus its effects will last much longer and indeed once in the soil it is difficult to imagine a process that will cause its sudden loss. The char can be mixed with manures and fertilisers and has been shown to improve the structure and fertility of the soil thus improving biomass production. There is some evidence that the char helps retain the fertiliser and decreases its run off.

The work from a range of organisations that are carrying out research into the benefits and costs associated with the use of agri-char was presented at the recent International Agri-char conference in NSW. The results reported showed a considerable variation in attempts to quantify the benefits, mainly, one suspects as it is ‘early days’ in the commercial production and field trials of this product. Work in WA for example valued the char in terms of increased wheat yield at $96/ha whilst most other researchers chose not to estimate the cost benefits. Never the less the works did indicate that there should be a quantifiable benefit in using char to improve plant yields.

A company that has been involved in the production of agri-char for some time is BEST Energies Australia based in NSW and they are examining the use of wood and paper mill waste to produce char. They use an externally heated paddle pyrolyser to produce the char which is then activated by subsequent gasification. The char so produced has a very large surface area per unit volume and in pot trials with the NSW DPI the early results were promising in terms of increased crop yield.

### 3.5.3 Fast Pyrolysis

Fast pyrolysis of biomass is one of the most recent renewable energy processes to have been introduced. The process can be carried out at medium to large scales and produces a liquid oil-like product that can be readily stored and transported. Bio-oil is a renewable liquid fuel and can also be used for production of chemicals.
TECHNOLOGY DESCRIPTION

Fast pyrolysis, used to yield a high fraction of bio-oil, employs a short residence time of 0.5 to 2 seconds and moderate temperatures - 400 to 500°C, in the pyrolysis chamber. The biomass particles and the evolved oil mist must be rapidly heated and cooled at approximately 500°C per second. Consequently, these processing conditions demand a fine feedstock of less than 3mm particle size that is relatively dry, with moisture content of less than 10% w.b. The key steps of the process are described below.

Feed drying
Typically a 10% moisture content in the wood is required. Waste low grade process heat would usually be employed, for example from the combustion of char and/or syngas.

Comminution
For most reactor types, wood particles have to be very small to enable the rapid heating required to achieve high liquid yields.

Pyrolysis vessel
The fine dry feed material is rapidly volatilised then condensed in a low oxygen atmosphere. There are six main types of fast pyrolysis vessels under development. These are illustrated in Figure 19 and the relative merits of each reactor type are shown in Table 17.

Char & ash separation
Almost all of the ash in the biomass is retained in the char so successful char removal gives successful ash removal. The char may be separated and sold as a separate product or combusted to provide process heat.

Liquids collection
Condensable gases must be cooled to collect the liquids. At large scales, quenching with an immiscible liquid such as a hydrocarbon or cooled liquid product is usually employed. The use of electrostatic precipitators is also under development. Careful process design and control is required to capture a full range of molecular weights.

Storage and transport
The bio-oil will require some local storage prior to local or remote use. Storage of bio-oil will usually require agitation to prevent settling and possibly some heating, depending on local environment.

PRODUCTS

Bio-oil is a liquid blend of hundreds of chemical species, which may be almost black through dark red-brown in colour, depending on its chemical composition. The density of the liquid is about 1200 kg per m$^3$ and is relatively acidic, with a pH of typically 2.5 to 4. The viscosity of the oil varies from as low as 25 cP up to 1000 cP depending on the water content, the amount of light ends, and the age of the oil. As a reference, water has a viscosity of approximately 1cP and fuel oils have viscosities in the range 800 to 12,000cP. While bio-oil is chemically stable, it will physically separate if left to settle (a timeframe of months is claimed). Upon stirring, with or without heat, the bio-oil will mix again into a homogeneous fluid.

Bio-oil contains a high level of oxygenated compounds, giving it a polar nature resulting in its poor miscibility with hydrocarbons. This can be overcome by using surfactants, enabling a stable emulsion to be formed with hydrocarbon fuels such as diesel. Bio-oil contains less nitrogen than petroleum products, and almost no metal and sulfur components, making them attractive from an emissions perspective. However, the high oxygen and water content of bio-oils makes them generally inferior to hydrocarbon fuels. A higher energy product, known as Bio-Oil Plus, can be produced by adding back the separated char into the bio-oil, in a finely ground form of about 8 microns in size.

The development and adoption of bio-oil as a blended transport fuel alternative has been hampered by a number of factors that are still to be overcome:

- Availability - limited supplies for testing
- Standards - lack of standards and inconsistent quality inhibits wider usage
- Incompatibility with conventional fuels
- Unfamiliarity of user
- Dedicated fuel handling needed due to settling
- Poor image

In Canada, bio-oil is partially or completely substituted for fossil fuels in some utility boilers. Immediate opportunities for industrial heating applications are also being explored. In primary industry, these include kilns and boilers in pulp and paper (see Figure 20), process heat in boilers in sawmills, metallurgy, oil and gas industries, and in secondary industries applications such as greenhouses and district heating.

![Figure 20: Canadian paper mill firing bio-oil in a lime kiln.](image-url)
Bio-oil developers have successfully tested bio-oil as liquid fuels in internal combustion engines and gas turbines, and bio-oil has been used commercially in boilers and other industrial combustors. As well as being emulsified with diesel, bio-oils have also been converted to synthetic hydrocarbon fuels via gasification and Fischer-Tropsch synthesis, although at a presently unacceptable energetic and financial cost. In the future, these bio-refining processes will probably be viable at large scales only.

Bio-oils have also yielded useful chemicals, mainly by extraction of resins using separation processes. Thermo-chemical conversion into higher value chemicals has also been performed although only at laboratory scale to date.

COSTS

Due to the small number and limited scale of existing pyrolysis oil production units, the economics of a commercial scale unit can only be estimated. Costs of bio-oil production depend on feedstock (pre-treatment) costs, plant scale, type of technology etc. Below are a number of different claims for the cost of production:

- $5-6/GJ ($85-94/ton) – Ensyn
- $6-7.50/GJ ($125/ton) - BTG (2002-03)
- $7-30/GJ ($125-500/ton), assuming feedstock costs $0-3.20/GJ ($0-165/t) (1999)
- $6.90/GJ - IEA study (Europe) in December 2006; see Table 18 for details.

**Table 18:** Production costs for bio-oil and char co-products compared with fuel oil prices. (Published in December 2006 IEA study in Europe)

Canada is regarded as a leader in pyrolysis oil technology and development, with two systems at the commercialization stage and two near commercialization. Current developments, as well as non-Canadian examples, include:

- DynaMotive Energy Systems (Canada) - Has a patented fast-pyrolysis process using a fluidized bed that converts forest and agricultural residues into pyrolysis oil. It is now expanding its 100 tonne per day pyrolysis oil plant, already the world's largest, and has recently constructed and commissioned a 200 tonnes per day plant at Guelph, (see Figure 21).

- Ensyn Corp (Ottawa) - Uses its high efficiency (around 75% by weight) core technology (Rapid Thermal Processing - RTP™) to transform biomass feedstock into more valuable chemical and fuel products. Ensyn first remove valuable chemicals form the bio-oil such as Natural Resins and other resin ingredients, leaving a clean residual bio-fuel that has been used commercially for industrial heat since the early 1990s. Ensyn’s bio-fuel can be blended with diesel and other petroleum fuels, although this has not been commercially implemented in transport fuels.

- Advanced Biorefinery Inc (Ottawa) - Has built and is testing a mobile fast pyrolysis unit to convert forest slash to pyrolysis oil using a process with a low parasitic load, and is now building a 50 tonnes per day modular plant to convert harvest waste and hog fuel from existing bark piles to liquid pyrolysis oil.

- Agri-Therm (Dorchester) - Is in the final stages of testing its 10 tonnes per day mobile pilot plant, which uses primarily agricultural residues in farm applications.

- Biomass Technology Group, BTG (The Netherlands) - Is in the final stages of commissioning a pyrolysis plant in Malaysia which produces 1.2 tonnes per hour of pyrolysis oil from palm oil residues.

- Renewable Oil Corporation, ROC (Darwin) - Is in the planning stages for the construction of a 200tonne per day pyrolysis plant in Darwin employing DynaMotive technology. The plant will be similar to the modular plant being built in Guelph,
Ontario, and is designed to process 200 tonnes per day of municipal green waste into pyrolysis oil. The bio-oil is initially intended to be used for co-generation, but ROC will also explore other value-added chemicals.

- It is believed that there is a plant in Victoria under development.

**Figure 21:** DynaMotive’s 200 tonne per day Plant in Guelph, Ontario, has an input of approximately 65,000 dry tonnes per year of biomass from waste construction and demolition wood and produces an energy output equivalent to 130,000 barrels of oil. ROC’s Darwin plant will be based on this modular design.

### 3.6 Direct Liquefaction

A wide range of process approaches initially developed in the 1970’s for coal, peat and wood sludge liquefaction have been researched and patented. Recent developments and commercialisation have targeted waste biomass. Direct liquefaction, the heat and pressure conversion process of producing liquid oil, is sometimes referred to as thermo-chemical conversion, thermal depolymerisation or simply liquefaction. By contrast, indirect liquefaction produces a liquid fuel by gasifying organic materials to syngas, followed by synthesis to ethanol, methanol, or other chemical compounds.

Direct liquefaction replicates nature’s conversion of biomass materials into petroleum under high pressure and temperature over millions of years. The thermo-chemical direct liquefaction process converts liquid slurry of biomass and organic materials to hydrocarbon oils and by-products, using high pressure (generally up to 200 atm) and temperature (generally up to 350°C), reducing processing times to minutes.76, 77

**TECHNOLOGY DESCRIPTION**

The main purpose of liquefaction is to increase the H:C ratio of the oil product relative to that present in the feedstock. A decrease of the O:C ratio is also necessary to achieve hydrocarbon-like products. Addition of a reducing gas, such as H2 or CO, is thus needed to increase the H:C ratio. In biomass materials, oxygen removal occurs via internal dehydration and decarboxylation reactions occurring during the initial pyrolytic stages. Another necessity of successful liquefaction is using uniform feedstock slurry in a liquid carrier, that is, a specific solvent or an aqueous system.77

In the case of sawmill residue, the woody biomass feed stock would be formed into a water based slurry with a uniform particle size and typically 20 to 30% solids. The slurry is then heated at elevated temperatures of 300 to 350°C with sufficient pressure to maintain the water primarily in the liquid phase (12 to 20 MPa) for residence times up to 30 minutes.
Carbon monoxide, hydrogen and other catalysts may be added to increase the hydrogen to carbon ratio, and reduce the oxygen to carbon ratio, thereby improving the hydrocarbon yields.

A series of separation processes remove the solids and water rich streams from the bio-derived oil.

PRODUCTS

The primary product is liquefaction oil, a free-flowing liquid that is a combustible mixture of oxygenated hydrocarbons. This organic liquid with reduced oxygen content (about 10%), can be converted to hydrocarbon fuels and commodity chemicals for products similar to those produced from petroleum.

Depending on feedstock and process details, yields of oil can range by mass weight from 26 to 80%. Estimated yields from processing 180 tonnes per day of turkey offal and grease waste at the Changing Worlds Technology bio-refinery based in Carthage, Missouri show approximately 63 tonnes per day (about 500 barrels) of bio-derived oil.78

For their Carthage, Missouri plant, Changing World Technologies has calculated an energy efficiency of 85% as measured by the energy in the combustible products that leave the plant divided by the total energy input (a sum of the energy in the dry feed and the electric power used).

At research level, liquefaction of ligno-cellulosic biomass (crop residues) yielded 60 to 80% bio-liquids.79 Research has shown that biomass feedstock with more lignin means more energy content resulting in higher oil yield.80

The primary by-product is water containing soluble organic compounds. Other by-products include steam, solid minerals and metals (as present in the feedstock), carbon char and inert and combustible gases. Depending on the feedstock, the solid minerals can include elements such as nitrogen, phosphorus, potassium and calcium. These products may be sold as soil amendments. Inert and combustible gases vary by feedstock and process, but mainly include CO\textsubscript{2}, CO and H\textsubscript{2}. When the combustible fuel gases CO and H\textsubscript{2} are produced, they may be recycled back into the process as a heating source, as process catalysts, or potentially as fuel for power generation. Steam can also be reused for process heat.

CAPITAL COST

Commissioned in 2003, a $20 million facility in Carthage, Missouri processes 180 tonnes per day of fats, bones, feathers, grease and oils from a ConAgra Foods turkey processing operation.

TECHNOLOGY STATUS

Development of biomass direct liquefaction has focused on slurried wastes such as sewerage, MSW, sludge and animal manure. A commercial scale plant was commissioned in 2003 and operational in 2004 in Carthage, Missouri to process 180 tonnes per day of animal waste material from a ConAgra Foods turkey processing operation. In 2002, Biomass Transformation Industries, LLC was seeking support for its extruder feeder liquefaction technology.

Liquefaction of ligno-cellulosic biomass (crop residues) has been successfully performed at research level. Using an ethylene carbonate catalyst, it has been found that hardwood lignin is more easily processed than softwood.

Research and commercialisation efforts for new reactor designs and processing are ongoing worldwide.
3.7 Hydrolysis

Currently, commercial scale production plants for fuel ethanol ferment readily available starch or sugars. Commonly, this is from corn, wheat and sugar cane (the main feedstock used in Australia). Ethanol can also be produced from ligno-cellulosic biomass, via hydrolisis followed by fermentation. Ligno-cellulosic biomass, referring to the stem parts of trees, shrubs and grasses, comprises a complex mixture of carbohydrate polymers from plant cell walls known as cellulose and hemi-cellulose, plus lignin and smaller amounts of other compounds generally known as extractives which include proteins, lipids and ash.

The use of the cellulose part of plants or trees (ligno-cellulose) is an attractive alternative feedstock as there is a greater mass of material available and this shall result in the elimination of the diversion of food crop to ethanol production. However the production of ethanol from wood waste is a far more complicated process.

TECHNOLOGY DESCRIPTION

In the production of ethanol from ligno-cellulose there are two general paths which may be taken – the sugar route which employs hydrolysis to break down cellulose and hemi-cellulose into sugars, followed by fermentation into ethanol and the gasification route.

Hydrolysis is done using one of three methods – dilute acid hydrolysis, concentrated acid hydrolysis and enzymatic hydrolysis. Dilute acid hydrolysis occurs in two stages, the first hydrolyses the hemi-cellulose, exposing the cellulose for hydrolysis in the second stage. During concentrated acid hydrolysis the feedstock is cooked in sulfuric acid creating a mash, which is then squeezed to collect the excess fluid and separated into ethanol and other by-products using simulated moving bed chromatography. Enzymatic hydrolysis uses enzymes to hydrolyse the feedstock using simultaneous saccharification and fermentation.

The gasification process is quite different to hydrolysis. The feedstock is input into a gasifier, where it is heated in a low oxygen atmosphere to produce a syngas which is purified and conditioned and put through the Fischer-Tropsch Process (described in section 3.5.1.2).

The choice of process is affected by many things including potential ethanol yield and feedstock type. It must be understood that at this point in time there is no clear winner with regards to technology options. Acid hydrolysis - both concentrated and dilute - of woods is old technology. A few of these types of plants were shut down after WWI because they weren’t economical. Once enzymes were discovered and developed, they offered the opportunity for higher yields and potentially lower costs.

If the feedstock for the process is "clean" - like hard wood - any of these pathways has the potential to work well. However, according to the NREL, gasification and concentrated acid hydrolysis both have the potential to work well for feedstocks that are heterogeneous, such as mixed wood wastes, urban green wastes and MSW. A dilute acid or enzyme hydrolysis route does not work as well at these extreme levels of heterogeneity.

PRODUCTS

Fuel ethanol is always at least 99.5% pure before it is denatured whether it comes from corn, sugar cane or biomass. The final ethanol product could be expected to have energy content (LHV) of 26.7GJ per tonne and density of 0.79 tonnes per cubic metre (21.2MJ per litre).
Table 20: Comparison of typical yields per dry tonne of wood feedstock for various products using gasification process

<table>

</tr>
<tr>
<td>Ethanol</td>
<td>600 L</td>
</tr>
</tbody>
</table>

The data shown in Table 20 is based on a feedstock with a calorific value of 19.7 GJ per tonne using the gasification process described earlier. However, there is a significant difference in the expected yield of the feedstock depending on the process and the company producing the ethanol. TECNIA expect to produce around 400L of ethanol per tonne of dry wood, using the FERMATEC continuous fermentation process, whereas the NREL are currently targeting 280L per tonne of dry wood using their gasification method.

In order to produce liquids, a minimum carbon content of 50% and ash content of less than 6% is needed. Hence it is necessary to know the chemical composition of the sawdust, before using it in this process; however, according to NREL, saw dust from a saw mill is expected to be suitable.

In each of the processes described earlier, lignin (a phenol polymer) remains as residual material after the sugars in biomass have been fermented to ethanol. It has energy content similar to coal and may be employed to power the operation, thereby reducing production costs. The lignin may also be used as an adhesive or binding agent, dispersant, emulsifier or sequestrant.

The energy density of lignin is subject to a significant variation which depends greatly on factors such as process used, moisture content and what else is in the residue. The properties of lignin also depend on whether it is produced from hard or soft wood; some these properties are shown in Table 21.

</table>

There are also a wide range of products which are made from lignin and/or sugars, including furfural, furans, glycols, MEK, adipic acid, ethylene, methanol, propylene, phenols, aromatics, dibasic acids and olefins.

A study was completed in 2005-06 on the development of new chemical products which could be produced from lignin. This study found a selection of small molecules that can be derived from waste lignin streams. A large library of microorganisms that produce chemicals from small molecules derived from lignin was generated and uses for some of the microbial products were identified.

There are also a variety of products which can be made from sugars such as the obvious ethanol, lipids, n-butanol, glycerol, acetone, acetylateddehyde, methanol, citric acid, itatonic acid, butanediol, fumaric acid, single cell protein, isopropanol, lactic acid, butanediol, acetic acid, lactic acid, butyric acid, acetylateddehyde, propionic acid, succinic acid, food grade sweeteners and other oxychemicals.
CAPITAL AND OPERATING COST

At this stage of development, ethanol production from wood is a very expensive process. One recent estimate of the CAPEX of a medium sized ethanol production facility (200 to 250 thousand green tonne per year) using concentrated acid hydrolysis was $70 million. This system is designed to produce around 61 million tonnes per year of ethanol if fed with radiate pine with bark. The system can also accept a variety of cellulosic materials such as bagasse, MSW and wood waste from forestry operations, although batches can not have a mixture of these products. A commercially feasible minimum plant size is thought to be around 150,000 green tonnes per year, although this depends on feedstock type and transport distances.

Some researchers in the field believe that it is far too early in the development stage to be estimating production costs.

Currently, fuel ethanol is sold on the futures market at $0.66 per litre, with production costs (non-cellulose base) varying from $0.27 to 0.87 per litre. It appears that in all cases, throughout the world, Governments subsidise the cost of production of fuel non-cellulosic ethanol and frequently impose tariffs to protect local production. The fuel, unlike gasoline, is not traded freely which it will ultimately need to be.

TECHNOLOGY STATUS

According to the Californian Energy Commission (PIER, 2007), at this moment, there is no integrated commercial plant anywhere around the world producing ethanol from lignocellulosic biomass. The New Zealand Government recently sponsored AES to complete a world wide survey of bio-oil and ethanol production plants. From this, AES concluded that the use of ligno-cellulose as a feedstock for ethanol production is not yet a commercially viable process. There are numerous pilot plants and laboratory tests being undertaken in North America and Europe; however the technology is still approximately 5 to 10 years away from the establishment of a commercial production facility. Listed below are a few companies who are active participants in the development of production processes for ethanol from wood:

- **BioEngineering Resources Inc.** – based in USA. BRI produce ethanol and electricity from any organic waste by producing a syngas and gasifying the gas, with the use of a biocatalyst.

- **Range Fuels** – Colorado and Georgia based. Have invented a two-step thermo-chemical process to produce cellulosic ethanol. This process can operate using a wide range of feedstocks (various types, sizes and moisture contents), which are used to produce a syngas then react in the presence of catalysts to produce ethanol. Range plans to begin construction this year and open the plant next year (2008) with a capacity of 20 million gallons a year. The facility then could be expanded to production of 100 million gallons a year.

- **Nova Fuels** – California based. Nova Fuels uses MSW, green waste and agricultural and forest biomass as a feedstock. They avoid the use of valuable feeds. Nova Fuels uses a gasification method to produce Novahol™, which is made up of a range of fuel alcohols and can be refined to ethanol, propanol, butanol and pentanol.

- **Arkenol** – Also based in California. Arkenol are a technology and project development company who focus on the construction and operation of world wide ethanol production facilities. The concentrated acid hydrolysis method described earlier is
based on their patented process. This technology has been licensed to numerous other companies.

- **Celunol** – USA based. Celunol uses a patented and proprietary technology to produce cellulosic ethanol. The key element of their process is a set of genetically engineered strains of Escherichia coli bacteria that are capable of fermenting essentially all the sugars released from many cellulosic biomass into ethanol.

- **TECNIA** – Portugal based. TECHNIA is able to provide a turn-key ethanol production facility with feedstock ranging from sugar to wood. They use a FERMATEC system which is different to the methods described above, as it is a continuous fermentation system. They are currently not represented in Australia.

- **NREL** – Based in the USA. NREL focuses most of its research on the enzyme and gasification routes as they believe there does not seem to be much of an opportunity for improvement in the concentrated acid approach as it is already fairly mature technology.

Given the current level of development this technology is not recommended for implementation, however it is expected that in 5 to 10 years ethanol production from wood waste will be feasible at a commercial scale.
3.8 Mulching and composting

Composting is an aerobic biological treatment process which converts solid organic material into a stable humus at elevated temperatures (40 to 60°C). Composting wood waste reduces the waste volume, detoxifies it and transforms the waste into a product that can be used as a soil amendment. Composting increases the organic matter content and improves the water-holding capacity, structure, texture and aeration of the soil. It also loosens clay soils, improves soil fertility and stimulates healthy root development in plants. A composting operation can be implemented at a plant site and requires limited knowledge, equipment and space; alternatively wood waste can be sold to mulching companies. The cycles of markets for residuals, mulch and sawdust, also are complementary; sales of sawdust increase in the winter, and sales of mulch increase in the summer.

Compost is used in many households throughout Australia as a method of recycling food scraps to nourish soil. However, composting can also be used at a commercial scale provided it is stored in a well drained area and is kept hot and dry. The Australian standard for composts, soil conditioners and mulches is AS4454.

The ideal carbon-to-nitrogen (C:N) ratio for composting is around 30:1. At lower ratios, nitrogen is supplied in excess and lost as ammonia gas, causing undesirable odours. Higher ratios mean that there is not enough nitrogen for optimal growth of the microbial populations, so the compost remains relatively cool and degradation proceeds slowly. Since wood chips or sawdust have a C:N of approximately 125:1 and bark 115:1, wood wastes from saw mills need to be combined with other organic waste streams to produce high quality compost. One option for achieving this mix is by first using the wood waste as animal bedding, this will add the required nitrogen hence creating high quality mulch.

Heat can also be extracted from compost piles (thermopiles) and used for other processes, by running pex tubing within the pile. Large piles of compost can reach 60 to 70°C. This operation is done commercially, but from this investigation a practical size of the pile and the amount the mulch needs turning to create a mature mix has not been found.

Composting is a method which has already been recognised by saw mills across Australia as a possible use for saw mill wood waste. Hence it has not been discussed in detail in this report.

3.9 Engineered Wood Products

Engineered or composite wood products are made by using adhesives to bind together wood strands, particles, fibres or veneers. These engineered products must be carefully designed in order to meet the standards for which they are to be used.

Waste wood from sawmills such as wood particles and fibers can be used to produce engineered wood products including:

- Oriented Stand Board
- Wafer Board
- Particle or Chip Board
- Masonite
- Medium Density Fiber Board
- Hard Board
- Mineral Bonded Particle Board and Fiber Board
- Wood Plastic/Polymer Composites – Monomers are “impregnated” in the wood and polymerised increasing the wood’s dimensional stability, hardness and abrasion resistance and making the material less moisture absorbent.
3.9.1 Scrimber

TECHNOLOGY DESCRIPTION

Scrimber is another type of engineered wood product. The process of manufacturing scrimber was originally developed by John Coleman at the CSIRO. It uses small diameter logs to produce structural timber. The trees are harvested and debarked, and then stems are crushed in a series of rollers in the “scrimming mill”, shown in Figure 22, producing a mat of interconnected and aligned strands which largely maintain the original orientation of the wood fibre. The “scrim” mat is then dried in a steam press, coated with water resistant adhesive, cut to length and collated.

![Figure 22: Scrimber production](image)

PRODUCTS

The result of the scrimber process is a high strength structural timber, shown in Figure 22. More than 85% of the log is utilized compared with the 40% utilization obtained by other milling methods. 93

![Figure 23: Scrimber](image)

TECHNOLOGY STATUS

The ‘scrimber’ technology is currently being applied by an American company that has patented their own scrimber process. It has been suggested that sawmill residues would be better used for lower strength composites or panels, with the possible exception of small diameter logs. 94
4 GOVERNMENT INCENTIVE SCHEMES

In order to decrease the effects of Greenhouse Gas Emissions the federal and state Governments and some private companies have set up funding or incentive schemes to entice the use and production of renewable energy. These schemes are constantly changing, with some expiring or running out of funds or new schemes being developed. The following list is all such schemes which could be found in August 2007. Before applying for these schemes the administering department should be contacted to find out if any changes have been made to the scheme, if it has expired or if it has exhausted all of its funding.

4.1 Federal Initiatives

The Australia Government released an Energy White Paper in 2004. This paper outlines the policies which are to be followed in order for Australia to control climate change and reduce Greenhouse Gas emissions. Within this policy there were many programs which the government put in place. A few of these programs are outlined in the following sections.

As a general rule co-firing – of non-native forest wood - is applicable under the federal schemes; however this should be confirmed when approaching the government departments for information or when applying for the initiatives.

4.1.1 Mandatory Renewable Energy Target

The Mandatory Renewable Energy Target (MRET) is a key element to the government's response to climate change and the reduction of greenhouse emissions. Sawmill residue is an eligible source under the Australian Government's Mandatory Renewable Energy Target. Information on how to participate in this measure can be found on the website of the Office of the Renewable Energy Regulator (ORER) http://www.orer.gov.au/index.html which is responsible for administering the scheme.

4.1.2 Renewable Energy Certificates

Renewable Energy Certificates (RECs) are an electronic form of currency which are created and traded by registered persons when their facility has created the required amount of energy from a renewable source. They may be eventually surrendered to demonstrate liability compliance against the requirements of the MRET. RECs may only be earned from the production of electricity, not from producing renewable energy fuels such as briquettes or pellets.

A generator of renewable electricity may apply for RECs with the ORER, when they have all of the required licenses (licensing is different in each state) and permits, by going to http://www.orer.gov.au/forms/ps-accredit.html and filling in the required forms. Once the power station has been accredited an application needs to be submitted and a registration number will be received. Following this, the power plant can earn RECs. The power station is also able to apply for provisional accreditation prior to gaining all of the required permits.

The ORER requires all records of where the wood waste for the power station has come from to be kept, as audits are randomly carried out.

4.1.3 Low Emissions Technology and Abatement

The Low Emissions Technology and Abatement (LETA) initiative is a $26.9 million measure to reduce Greenhouse Gas emissions over the longer term by supporting the identification and implementation of cost effective abatement opportunities and the uptake of small scale low emission technologies in business, industry and local communities. This program is administered by the Australian Greenhouse Office (AGO). For more information see http://www.greenhouse.gov.au/leta/index.html.
4.1.4 Renewable Remote Power Generation Programme

The Renewable Remote Power Generation Program (RRPGP), another AGO administered scheme, provides rebates for the installation of renewable generation equipment in remote parts of the country that presently rely on fossil fuel for electricity generation. Depending on location, a project can be eligible for a rebate of up to 50% of the cost for projects up to 2MWₑ in size. Further information can be obtained by calling 1300 137 880 or going to http://www.greenhouse.gov.au/renewable/rrpgp/index.html.

Table 21 shows which Government office administers the RRPGP in each state:

4.1.5 Renewable Energy Development Initiative

The Renewable Energy Development Initiative (REDI) is a competitive grants program supporting renewable energy innovation and its early-stage commercialisation. The program provides matching grants from $50,000 up to a limit of $5 million for eligible renewable energy technology projects extending up to three years. REDI applications are considered on a continual assessment basis designed to assist the quality of applications through greater interaction of customers with AusIndustry customer service managers.

4.1.6 Low Emissions Technology Demonstration Fund

The $500 million Low Emissions Technology Demonstration Fund (LETDF) is also administered by AusIndustry and is a flagship initiative of the Australian Government's Energy White Paper: Securing Australia's Energy Future. The objective of the fund is to demonstrate the commercial potential of new energy technologies or processes or the application of overseas technologies or processes to Australian circumstances to deliver long-term large-scale greenhouse gas emission reductions. This fund covers renewable and fossil fuel supply technologies as well as energy efficiency, and can be for either stationary or transport energy.

4.1.7 Ethanol Production Grants

The Ethanol Production Grants (EPG) program is an eligibility-based program administered by AusIndustry. EPGs are paid to ethanol producers at a rate of 38.143 cents per litre. To
claim the grant, the ethanol must be produced entirely in Australia by the grant recipient from biomass feedstock, which is to be used in, or as, a transport fuel in Australia. For more information see [http://www.ausindustry.gov.au/content/level3index.cfm?ObjectID=B1EF3084-DB7A-4B56-AE6978EBA8AB3F09L2Parent=AE8901E5-7CB8-4143-A3BF33B2423F9DA6](http://www.ausindustry.gov.au/content/level3index.cfm?ObjectID=B1EF3084-DB7A-4B56-AE6978EBA8AB3F09L2Parent=AE8901E5-7CB8-4143-A3BF33B2423F9DA6).

4.1.8 Industry Co-operative Innovation Program

The Industry Cooperative Innovation Program (ICIP) is a merit based grants program aimed at encouraging business-to-business cooperation on innovation projects both within Australia and internationally that enhance productivity, growth and international competitiveness in Australian industries. For a mill to be able to apply for this program they would need to be working with another mill/organisation. This program is also administered by AusIndustry. For further details refer to [http://www.ausindustry.gov.au/content/level3index.cfm?ObjectID=91F9C943-E61A-4075-BB6CE9989586B143L2Parent=AE8901E5-7CB8-4143-A3BF33B2423F9DA6](http://www.ausindustry.gov.au/content/level3index.cfm?ObjectID=91F9C943-E61A-4075-BB6CE9989586B143L2Parent=AE8901E5-7CB8-4143-A3BF33B2423F9DA6).

4.1.9 Renewable Energy Equity Fund

The Renewable Energy Equity Fund (REEF) – administered by AusIndustry - provides venture capital and managerial advice for small, innovative renewable energy companies. This includes companies which are commercialising direct or enabling renewable energy technologies and services. The company receives capital, managerial expertise and enhanced business reputation as a result of the REEF investment. In return for the provision of capital, the fund manager acquires a part-ownership of the company and usually a seat on the Board of Directors. The Commonwealth contributed $17.7m to establish the fund, CVC REEF Ltd, which is matched by private sector funding of $8.8m for a total fund of $26.6m. For more details see [http://www.ausindustry.gov.au/content/level3index.cfm?ObjectID=BFD445F4-56A3-4D40-B010321DE18F422FL2Parent=AE8901E5-7CB8-4143-A3BF33B2423F9DA6](http://www.ausindustry.gov.au/content/level3index.cfm?ObjectID=BFD445F4-56A3-4D40-B010321DE18F422FL2Parent=AE8901E5-7CB8-4143-A3BF33B2423F9DA6).

4.1.10 Cleaner Fuels Grant Scheme

The Cleaner Fuels Grant Scheme applies to the manufacture and importation of fuels that have a reduced impact on the environment. For example, currently, biodiesel and premium unleaded petrol which has 50mg per kg of sulfur or less (PULP) are eligible cleaner fuels. This scheme is administered by the Australian Taxation office. For more information on the scheme refer to [http://www.ato.gov.au/businesses/content.asp?doc=/content/38324.htm&pc=001/003/044/008/006&mnu=12130&mfp=001&st=&cy=1](http://www.ato.gov.au/businesses/content.asp?doc=/content/38324.htm&pc=001/003/044/008/006&mnu=12130&mfp=001&st=&cy=1).

4.1.11 GreenPower

GreenPower is the only national renewable energy accreditation program endorsed by the Government. This scheme does not provide any financial aid to energy suppliers except for adding approximately $1 to 2 per MWh to the RECs earned for the renewable energy. This program does however allow the company to be affiliated with the name “Green”, which may be desirable for some mills.

For plants larger than 1MW, there is a $1000 application fee and following the first year there is a $1000 per year accreditation fee. For plants smaller than 1MW there is no fee to be accredited. A new applicant plant may need to arrange a power purchase agreement with an energy provider, such as Origin, prior to plant construction to ensure they will receive financial benefits.

4.1.12 Greenhouse Gas Abatement Programme
The Greenhouse Gas Abatement Programme (GGAP) leverages private sector investment in activities or technologies through projects. There were 3 funding rounds for GGAP, these have concluded and no other funding rounds are being offered.

4.2 Australian Capital Territory Initiatives
There is only one state scheme which operates in the Australian Capital Territory (ACT). The ACT has not had a forestry industry since the 2003 bushfires which destroyed their plantation forests.

4.2.1 Greenhouse Gas Abatement Scheme
Refer to section 4.3.3, Greenhouse Gas Abatement Scheme below in New South Wales initiatives.

4.3 New South Wales Initiatives
4.3.1 NSW Renewable Energy Target
Similarly to the MRET, the New South Wales Renewable Energy Target (NRET) imposes a target on electricity retailers and includes renewable energy certificate trading and an enforceable penalty for non-compliance where retailers fail to meet their targets. The NRET requires a proportion of electricity consumed by NSW to be sourced from renewable electricity generation anywhere in the National Electricity Market. This target includes the Greenhouse Gas Abatement Scheme and GreenPower. NRETs are administered by the Department of Water and Energy. For more information on the NRETs refer to [http://www.deus.nsw.gov.au/Publications/NRET%20Explanatory%20Paper%20FINAL.pdf](http://www.deus.nsw.gov.au/Publications/NRET%20Explanatory%20Paper%20FINAL.pdf).

4.3.2 NSW Renewable Energy Certificates
The NRET is currently before parliament; hence details of the NRECs have not yet been released. However they are to be very similar to the Victoria Renewable Energy Certificates. If a mill wishes to earn both NRECs and RECs they may do so, however they may only claim one of the certificates per MWh of energy produced. For more information see [http://www.deus.nsw.gov.au/Publications/NRET%20Supporting%20Information%20v14.pdf](http://www.deus.nsw.gov.au/Publications/NRET%20Supporting%20Information%20v14.pdf).

4.3.3 Greenhouse Gas Abatement Scheme
The Greenhouse Gas Abatement Scheme (GGAS) is regulated by the Independent Pricing and Regulatory Tribunal (IPART) in both NSW and ACT. GGAS requires NSW and ACT electricity retailers and certain other parties to meet mandatory targets for reducing or offsetting the emission of Greenhouse Gases from the production of the electricity they supply or use. Within this scheme New South Wales Greenhouse Abatement Certificates (NGACs) are produced (1 NGAC is equivalent to 1 tonne of offset greenhouse gas) and may be traded (similarly to RECs). For more information on this scheme see [http://www.greenhousegas.nsw.gov.au/](http://www.greenhousegas.nsw.gov.au/).
4.3.4 Climate Change Fund
The Climate Change Fund is currently under development by the Department of Environment and Conservation of New South Wales. This program will total $310 million dollars over 5 years with $40 million being allocated to the Renewable Energy Development Fund for pilot and demonstration projects, such as solar and geothermal power stations. For more information on this fund see [http://www.environment.nsw.gov.au/grants/ccfund.htm](http://www.environment.nsw.gov.au/grants/ccfund.htm).

4.3.5 Climate Action Grants Program
The Climate Action Grants Program is administered by the Department of Environment and Climate Change (DECC). The Climate Action Grants Program supports projects that assist the development and adoption of technologies, processes and practices that reduce greenhouse gas emissions or help the NSW community to adapt to the impacts of climate change.

The Climate Action Grants ($10 million over four years) assist the development and adoption in NSW of greenhouse technologies in the areas of waste, transport, forestry, agriculture, industry processes or land use; however not including energy generation and use. For more information see [http://www.greenhouse.nsw.gov.au/funding_programs/nsw_funds/climate_action_grants](http://www.greenhouse.nsw.gov.au/funding_programs/nsw_funds/climate_action_grants).

4.3.6 Government Assistance
The regional offices of the NSW Department of State and Regional Development offer Government assistance. To find out more or apply for such assistance contact the Department on (02) 9338 6600.

4.4 Northern Territory Initiatives
The Northern Territory has no commercial 'standing' timber mills and only a very few portable mills in commercial operation, and thus there is no incentive schemes in place by any Northern Territory Government agency to encourage better use of wood waste.

4.5 Queensland Initiatives
The Queensland Government recently released *Climate Smart 2050*. This document outlines schemes which the state Government shall be implementing in order to reduce the effects of global warming. A "$50 million Queensland Renewable Energy Fund" and the "Queensland renewable and low-emission energy target of 10% by 2010" are examples of these schemes. This document can be found online at [http://www.thepremier.qld.gov.au/library/pdf/climate/ClimateSmart_2050.pdf](http://www.thepremier.qld.gov.au/library/pdf/climate/ClimateSmart_2050.pdf).

The Queensland Department of State Development may be able to offer assistance, however at this time they do not offer any specific schemes for renewable energy.

4.6 South Australian Initiatives
South Australia has a target of 20% of the State’s power coming from renewable sources by 2014.

4.6.1 Regional Development Infrastructure Fund
The South Australian Government provides financial support (grants or loans) through the Regional Development Infrastructure Fund (RDIF) to projects that are a priority for economic development, with broad benefits for an industry or region. The next closing date for
submitting applications is 30 November 2007. Proposals claiming significant state benefit may be considered outside of the closing date. Further details of this scheme are available at http://www.ora.sa.gov.au/

### 4.6.2 Equity Ready Program
The Venture Capital Board has an Equity Ready Program which aims to educate and assist companies in the process of gaining external investment in order to achieve business growth. Further information is available at http://vcbsa.com.au/

### 4.6.3 The Premier’s Science and Research Fund
The Premier’s Science and Research Fund (PSRF), which now incorporates the former Sustainable Energy Research Grants Program (SENRAC), is an initiative of the South Australian Government and the Premier’s Science and Research Council. The fund was established to facilitate investment in key science and research initiatives of strategic and sustainable value to the state. It aims to make transformational investments that have a demonstrable potential to generate significant and sustainable economic, social or environmental benefits for South Australia. Further information is available at http://www.innovation.sa.gov.au/sti/councils_and_boards/psrc/premiers_s_and_r_fund.

### 4.7 Tasmanian Initiatives
From research completed, no incentives schemes were found to be offered by the Tasmanian Government.

### 4.8 Victorian Initiatives

#### 4.8.1 Victorian Renewable Energy Target
Like the MRET and NRET, under the Victorian Renewable Energy Target (VRET), all electricity retailers and wholesale buyers in Victoria will have a legal liability to contribute towards the generation of additional renewable energy and meet their obligation by acquiring renewable energy certificates. The VRET scheme is administered by the Essential Services Commission (ESC). According to Rule 1 of the VRET energy produced from sawmill wood waste is eligible for use. For more information refer to http://www.esc.vic.gov.au/public/VRET/.

#### 4.8.2 Victorian Renewable Energy Certificates
There are VRECs which are different from the federal RECs. An energy production facility may not claim or be registered for both VRECs and RECs.

The Victorian Renewable Energy Certificates (VRECs) are a form of currency initiated by the Victorian Renewable Energy Act 2006 (the Act). VRECs are created by registered persons, validated by the Commission, traded between parties and eventually surrendered to the Commission to demonstrate liability compliance against the Act.

A VREC must be registered by the Commission before they are considered valid. The Commission maintains a register of VRECs which is published on their website. A certificate is only valid as a VREC if listed in this register.

A VREC must be created by the end of the year after the year in which the generation of electricity for the VREC occurred. VRECs remain valid until surrendered to meet a liability and

Co-firing of renewable resources is applicable under the VRET and VRECs. However, it is only for new capacity energy that is energy from a new facility or additional energy produced in an existing facility that is produced from the renewable resources which may be claimed for VRECs. The ESC would need to consider each plant on a case by case basis.

4.8.3 Renewable Energy Support Fund

The Renewable Energy Support Fund (RESF) is a key initiative of the Victorian Greenhouse Strategy and aims to facilitate and demonstrate innovative renewable energy projects that contribute to reducing Victoria's Greenhouse Gas emissions. Energy from renewable energy sources is not confined to electricity generation. Renewable resources can also be converted to heat energy, as seen in solar heating and geothermal projects.

The RESF is funded through the Victorian Greenhouse Strategy and can provide funding of up to 20% of the capital cost of projects. Projects must demonstrate innovation and local market development potential in the delivery of renewable energy to Victoria. Eligible projects may produce heat or electricity from a renewable energy source, but must be located in Victoria, reduce greenhouse gas emissions, have a maximum capacity between 20kW and 5 MW for electricity projects or between 70 MJ per hour and 20GJ per hour for thermal projects, use technically proven technology that is innovative in its application in Victoria and show the potential for further application in Victoria. The amount of support available for a project is based on the level to which the project satisfies selection criteria.

4.8.4 Sustainability Fund

The Sustainability Fund is designed to support projects that are innovative and foster sustainable resource use and have economic and social benefits for Victorians. Since 2004, the Fund has provided $42 million to support 82 diverse projects in schools, businesses, local government and community groups.

4.9 Western Australian Initiatives

The Department of Industry and Resources is available to companies in Western Australia in providing advice and guidance for setting up or expanding their capabilities; however at this stage they do not offer any funding.

4.9.1 Strategic Waste Initiatives Schemes

The Strategic Waste Initiatives Scheme (SWIS) is aimed at providing support and encouragement to business and industry, local government, community groups and individuals in tackling priority waste issues. If a mill was to be using wood waste which would otherwise go to landfill or be used in other inefficient manners then it would be eligible to apply for this scheme.

This scheme is administered by the Department of Environment and Conservation. For more information see http://zerowastewa.com.au/ourwork/supportschemes/swis/ or call Paul Ward on 08 6467 5320.
4.10 Private Funds
4.10.1 Centre for Energy and Greenhouse Technologies

The Centre for Energy and Greenhouse Technologies (CEGT) provides investment funds and support services for the development of new sustainable energy and greenhouse gas reduction technologies.

5 OPPORTUNITY ANALYSIS

5.1 Energy products

Sawmill wood residues may be used for their energy value in a variety of ways. Conversion to solely electricity is possible from scales of tens of kW upwards. Electricity generated in small scale systems at sawmills may be used for plant power and the excess electricity may be sold to the grid or to nearby neighbours. The best price will be gained by displacing purchased electricity, which will effectively yield retail prices, compared to surplus electricity sold to the grid, which will only yield considerably lower wholesale prices.

Generally, conversion efficiencies will increase and the cost per kW or MW of generation capacity will decrease with increasing scale. At larger scales, parasitic losses are proportionally smaller and heat recovery systems are more efficient and cost effective. Overall electrical efficiencies at scales less than 1MWₚ are likely to be less than 15%. Systems greater than about 5MWₑ can utilise steam turbines and will likely have electrical efficiencies of 15% to 25%. Large scale power stations typically have electrical efficiencies of 30 to 40%.

Figure 24 shows the effect of system conversion efficiency on electrical output from annual quantities of sawmill residue. A 10MWₑ steam turbine system may be expected to have an overall conversion efficiency of 20% and would require around 100,000 tonne per year of dry hardwood residue.

![Figure 24](image)

**Figure 24:** Average electrical output for various conversion efficiencies from hardwood residue with gross heating value of 14MJ/kg (~25% moisture content wet basis). The green band represents the likely conversion efficiency for a given system capacity.
Electricity generation at small scales – up to a couple of MW_e – is most suited to technologies such as reciprocating steam engines or Internal Combustion (IC) engines, micro-turbines and fuel cells. However, at present gasified wood fuelled micro-turbines and fuel cells are not commercially available, leaving either reciprocating steam or IC engines. These systems are commercially available, although there are a limited number of suppliers, particularly in Australia.

Electricity generation via steam turbines is feasible above about 5MW_e, although it is marginal below about 10MW_e. These systems will achieve higher conversion efficiencies than the small scale systems and improve as they get larger.

To utilise larger scale systems and thus increase electricity conversion efficiency the following approaches may be employed:

1. Collect larger quantities of biomass into a single power generation system. Most sawmills in Australia have between 10,000 and 100,000 green tonnes per year input and will individually produce around 5,000 to 50,000 green tonnes per year of residue. Biomass fuelled electricity generation systems are not likely to be economically viable below 5 to 10MW_e scale which means that collection of up to or over 100,000 green tonnes per year of residue would improve viability. This may be achieved through cooperative effort by two or more mills.

2. Co-fire biomass with fossil fuels – co-firing of solid wood in large scale utility boilers competes with fossil fuels such as coal, natural gas or diesel. Coal is dominant in Australia with around 43GW_e installed capacity. Natural gas is also significant with around 11GW_e installed capacity. Coal is relatively cheap and difficult to compete with, particularly since co-firing sawmill residue would only fractionally displace coal meaning that savings in coal mining infrastructure and operating costs will be marginal. The co-firing of gasified wood will compete with mostly natural gas, which is also cheap and abundant in most parts of Australia. Economic viability of biomass co-firing will rely on identifying power generation sites where fossil fuels costs are high (for example, in remote areas) and/or exploiting government subsidies to fund the cost differential.

Both of these options will usually involve transporting biomass over relatively larger distances, incurring significant cost due to the low heat value and bulk density of wood biomass. Additionally, transport vehicles burn fossil fuels and generate net GHG emissions, negating the environmental benefits gained from bio-electricity. Figure 25 shows the typical costs for transporting woodchips by road using 60m³ and 80m³ capacity B-doubles. As an example, transporting hardwood chips 200kms is likely to add approximately $18 to $23 per tonne or $1.10 to $1.50 per GJ to the material cost. Of course, using back-loads or long-term contracts may reduce these costs.
Technologies that increase the energy density of the wood residues can significantly reduce transport costs and improve the viability of transporting biomass large distances. Table 22 shows the volumetric energy density for a range of potential energy products from sawmill residues. When compared to most fossil fuels, the volumetric energy density of wood chips, shavings and sawdust is very low at typically 3 to 9 GJ per m$^3$. Even brown coal, which has a relatively low energy density on a wet basis, due to its high moisture content, is typically around 8GJ per m$^3$ at the top end of the woodchip range. Coal is made viable because it is abundant and concentrated enabling stationary power generation to utilise relatively inexpensive conveyor based transport.

Pelletising or briquetting are probably the simplest and least expensive methods of increasing bulk density and thereby volume energy density. Pelletising or briquetting will increase the energy density to approximately 12 or 13GJ per m$^3$. 

**Figure 25**: Typical round-trip transport costs for 80m$^3$ B-double carrying woodchips. Transport costs assumed to be $1.60 per km for short trips and $1.75 per km for medium to long trips, with no back-load. Wood chip bulk density is assumed to be 0.50 tonne per cubic metre and a bulk energy density of 8GJ per tonne.

a. Sample ID 71 Residue from Timber mill: Eucalypt sawdust. The main species used at the timber mill is spotted gum.

Energy conversion efficiency may be increased by recovering both heat and electricity. This strategy allows 70 to 80% of the energy to be used where there is a need for low grade heat. Heat applications include:

- Process heat (for example, kiln drying)
- Space heating for residential, office, factory, etc
- Heat source for absorption chillers
At many sawmills, kiln drying is a high energy consumption process, accounting for approximately 70 to 90% of the mill's total energy needs. Kiln heating may either be by indirect means, transmitted by steam, hot water or thermic oil or by direct firing, whereby the combustion gases or hot air from a source exterior to the kiln are directed into the kiln. Although direct firing has been proven to give greater heat efficiency compared to the indirect method, the need to vent the combustion gases does constitute a heat loss.\(^4\)

The cyclic demand for heat, particularly steam, in wood drying kilns places constraints on the electricity generation portion of the plant. As outlined in section 3.4.6 a reciprocating steam engine would be more suitable at scales less than 2MW\(_e\) where there is a varying supply of steam. Conversion efficiencies can be maintained throughout the drying cycle due to their good turn-down performance. Alternatively, a combined gasification and internal combustion engine unit may be used to generate electricity and useful waste heat. These systems are being widely tested although very few commercial units are available. Combusting wood pyrolysis gas in micro-turbines is even less mature with trials in their infancy. Fuel cell based CHP systems, even with fossil fuels, are still largely at the technology demonstration stage and commercial units are scarce.

Conversion of cellulosic biomass to liquid fuels (Biomass-to-Liquid or BTL) is an emerging set of technology options. BTL technologies include hydrolysis and fermentation, gasification and F-T conversion, fast pyrolysis or direct liquefaction and other variants, as outlined in section 3. These products potentially represent significantly higher value than solid fuels, particularly in Australia, because they can be used for transport fuels rather than being limited to stationary power. Solid fuels are largely limited to applications for stationary heat and power generation, where it competes directly with cheap coal or natural gas. Importantly, BTL fuels have higher volumetric energy densities than the solid fuel variants, at 20 to 24GJ per m\(^3\). The higher heating value and higher energy density makes the transport of these fuels over large distances more economically viable.

The technologies for the conversion of sawmill residues to ethanol via hydrolysis are not considered commercial at present and are probably 5 to 10 years away. By comparison, there are few technical challenges to solve with biomass gasification routes however there are economic barriers, which are shown in Table 23.

Fast pyrolysis of sawmill residues into bio-oil is technically feasible, and has been commercialized by one or two Canadian companies. The cost projections for bio-oil production at moderate scales (200 tonnes per day) are competitive with fossil fuels for heating applications in Europe, however for heating in Australia with natural gas costs as low as $4 per GJ (for large industry users), there is a limited market. The blending of bio-oil with diesel for use in stationary power applications has been successfully but not widely trialed. The conversion and refinement of bio-oils to synthetic transport fuels is still under development and is likely to be some years away from commercialization.

According to the Asian-Pacific Forestry Commission, the most attractive option for using large volumes of sawmill waste is producing charcoal briquettes and using them for cogeneration.\(^{20}\)

a. Assuming 0.60 EUR = 1.00 AUD

An assessment of the markets for pyrolysis oil and char in Europe found the following to be the best options $^{105}$:

- pulp mill lime kilns, cement kilns
- co-firing in coal, oil and natural gas power plants (many natural gas power plants are configured already to run on alternate fuels)
- district heating plants, chiefly those with unloading facilities on a coast, or inland waterway

In Germany, policies favour small power, so substitution of pyrolysis oil for diesel in new power plants of up to 20 MW is an excellent and growing market. In Australia some of these same opportunities exist as well as some additional ones such as co-firing in biomass fuelled power generation or co-generation systems, particularly where there is a shortage or seasonal demand for alternate biomass fuels, such as in the sugar industry.

If wood pellets were to be produced for the purpose of exporting, obviously the cost of transportation of this fuel would be a major part of the costs involved. In order to export, there are three charges involved, the loading rate, the charter rate and the unloading rate. These charges differ depending variables such as the type of product being exported.
5.2 Non-energy products

Sawmill residue has more uses than merely as an energy product. There are a large number of non-energy based commodities which can be produced, ranging from chemicals to engineered wood products.

The conversion of sawmill residues into useful chemicals, particularly to displace products derived from fossil fuels, is one area of research and development. The first products that have been brought to market are industrial resins and food flavourings, derived from bio-oil as a co-product with bio-fuels for stationary heat and power. A wider range of chemical products are being developed from bio-oil but these are not yet commercially produced. Other products which are under development are those formed as co-products in the production of cellulosic ethanol. This means that lignin may be used for more than its energy content and instead for potentially producing a whole range of chemicals. Processes under development are focusing on the conversion, firstly into intermediate or platform chemicals from which products such as specialty chemicals, commodity chemicals, resins, pesticides or herbicides may be derived. Research in this area is promising but confined largely to laboratories, hence there is little cost modelling available.

The production of non-energy related char products from wood via thermo-chemical conversion may be carried out independently or as a co-product in the generation of heat, power or liquid fuels. The use of char for filtering or as a metallurgical reductant is not new but may be of interest to traditional users as an environmentally friendly alternative to fossil fuel derived carbon.

The use of wood derived char as a soil additive to increase soil carbon content and potentially enhance crop yields is a relatively new concept. Additionally, this concept is being explored as an alternative means to sequester carbon for considerably longer periods than in natural biological cycles, without the risks associated with gaseous geo-sequestration. The use of agri-char is an area of growing interest, research and funding, but at this stage there is only sketchy evidence of agricultural benefits and no established market or commercially available plants. At present, there is no official recognition from regulatory bodies of char sequestering as a means of Greenhouse Gas reduction and consequently there are no incentives available.

Of lesser importance in this review, but worth noting are some novel engineered wood products emerging that may be practical alternative uses for some residues.
5.3 Case Study of Wood Waste from Generic Saw Mills

If we consider three different sized Australian mills, nominally hardwood, with kiln drying and across a range of typical sizes, the residue types and quantities would probably be as laid out in Table 25. The next step would be to explore the specific characteristics of each mill; its location, neighbours, relevant community features, operation hours, energy demand, fuels and costs.

These figures relate to the amount of logs input into the mill. The logs may or may not be debarked on site. From these figures and the amounts of waste streams produced mentioned earlier the following approximations were made:

<table>

</tbody>
</table>

Mill C – Small mill

- Where there is an on-site, neighbouring or nearby community demand for heat and/or cooling, particularly if energy costs are high (for example remote areas), consider burning residues for heat value. Value may be generated in the form of steam, hot water, hot gases, hot oil, or cooled air and water via absorption chillers. New opportunities may arise over time as energy costs fluctuate and increase over time.

- If there were also a demand for and a high cost of electricity, consider a small scale CHP system. Electricity generation at this scale would suit using a boiler and steam engine or a combined gasification and IC engine. These plants are not likely to be economically viable from savings in electricity alone, but subsidies are available for new renewable generation capacity, generation from waste and for remote distributed generation (RRPGP).

- Otherwise consider briquetting fines and selling locally for domestic heating, as is done by the Whittlesea saw mill. The process equipment is relatively cheap and easy to operate. Fuel characteristics do not require tight control for the domestic market compared to pellets, which typically end up in large scale furnaces.

- Technology decisions will be dependent on mill operation hours, type of residue mix, quantity of residue and current market value of various waste streams.

Mill B – Medium mill

- As for Mill C, look for opportunities for on-site, neighbouring or nearby community demand for heat and/or cooling, particularly if energy costs are high.

- Look for opportunities to merge supplies with neighbouring sawmills or biomass residue producers (for example forest residues or thinnings, engineered wood product residues, D&C residues, agricultural residues). CHP plant could become viable if sufficient compatible residue quantities can be gathered.
• Consider pelletising and marketing within Australia or exporting. A mobile pelletising plant could be shared between sites (with each site stockpiling) to share capital and operating know-how, quality control expertise and testing equipment. Exporting costs could also be shared.

• Look for a nearby use of wood fuel, such as co-firing utility boilers, lime kilns, and cement kilns. Viable transport distances may be reduced by pelletising.

Mill A – Large mill

• Look for opportunities for heating, cooling or CHP. At larger scales, efficiencies will be improved by using turbine technologies and heat recovery systems.

• As for Mill B, look for opportunities to merge supplies with neighbouring sawmills or biomass residue producers (for example forest residues or thinnings, engineered wood product residues, D&C residues, agricultural residues)

• Look for a nearby use of wood fuel, such as co-firing in utility boilers, lime kilns, cement kilns or bagasse furnaces. Viable transport distances may be reduced by pelletising.

• As for Mill B, consider pelletising and marketing within Australia or exporting. A mobile pelletising plant could be shared between sites (with each site stockpiling) to share capital and operating know-how, quality control expertise and testing equipment. Exporting costs could also be shared.

• Look for opportunities to combine residues to produce CHP – enabling more efficient technologies to be employed. Quantities above 150,000 green tonnes per year could become competitive with grid electricity and normal fuel costs for heating, however there are many incentive schemes that could be applied for depending on specific circumstances.

• Consider bio-oil production. The technology has been commercialised by one or two Canadian companies, with subsequent conversion to electricity or industrial chemicals; there is a plant in planning in Darwin which will consume up to 200 tonnes per day of feedstock. Markets for bio-oil are not yet established but markets for derived products may be readily accessible.
5.4 Overall assessment

An overall assessment of the potential technologies for using sawmill residues has been given in Figure 26. In making this subjective judgement, the economic benefit of a product is intended to reflect the potential value of each product to a sawmill operator in Australia. Technology readiness is intended to reflect the suitability of available expertise and equipment for generic Australian sawmills. Clearly, an option is more appealing if it is closer to the bottom right corner (green corner).

![Figure 26: Qualitative assessment of economic benefit of each product versus technology readiness](image)

There is a relatively large potential market for chemical products and they represent the highest value of all options reviewed, however they are the furthest from commercialisation. Platform chemicals will probably be commercialised before chemical products but are of marginally lower value.

Bio-fuels such as cellulosic ethanol, Fischer-Tropsch diesel or other Biomass-To-Liquid fuels offer relatively high value but are still largely in the research stage, with ethanol (arguably the most advanced) being an estimated 5 to 10 years from commercialisation. Bio-oil, situated in the middle of the figure, is an evolving technology with one or two commercial players. Bio-oil is a suitable product for a wide range of stationary heat and power applications; with additional processing the product can attain higher value as a transport fuel or chemical products. Industrial resins and food flavourings have been commercially manufactured from bio-oil.

Agri-char is of limited value and is hindered presently by a lack of hard evidence for soil enhancement; however, there is a potentially massive market if significant benefits in agriculture or carbon sequestration were proven.

Electricity produced from wood waste has moderate value in most parts of Australia and technologies for the efficient conversion of wood waste into electricity are limited at size ranges commensurate with typical residue quantities from Australian hardwood sawmills. Government incentives, such as RECs, can provide additional effective value for bio-electricity. Heat is also relatively inexpensive in most parts of Australia due to an abundance of natural gas, however heat can be derived from sawmill residue cheaply and efficiently, so the benefit is considered moderate. If both heat and electricity are co-generated from sawmill
residue, then overall conversion efficiencies are high (provided the mix of roughly 3:1 heat to electricity can be used gainfully) and the combined benefit is higher than each individually.

Briquettes in most parts of Australia are of limited value and there is a relatively small market for residential heating, which competes with natural firewood. As firewood becomes scarcer, this product may increase in value and the market may grow. Pellets are more expensive to produce than briquettes however they are easier to transport in bulk and can be used in a wider range of applications. The domestic market is relatively small at present and is unlikely to grow; however, there is a large potential export market if economic shipping rates can be secured.

a. The maximum steam flow rate through the biggest Spilling steam engine, a 6-cylinder-type, is for the inlet and outlet pressures stated. In this case it would need to be decided either to limit it to that size or to use two 4-cylinder-engines or one 2-cylinder-engine and one 6-cylinder-engine or to use a steam turbine. With two engines (2 x 4-cylinder or 1 x 6-cylinder and 1 x 2cylinder) the total electrical output with 18 tonnes per hour of steam flow would be approximately 1520kW and the total thermal output approximately 10,350kW.

Note: These prices do not include engineering, documentation, packing, transport and commissioning.
APPENDIX II
The following data sheets are intended to be an easy reference tool for sawmill operators to quickly assess the suitability of these options for their particular circumstances.

### Wood Briquettes or Synthetic Logs
- Lower energy density than liquid fuels and pellets, but higher than wood chips
- Much lower market value than pellets, but cheaper to produce

<table>
<thead>
<tr>
<th>Typical plant capacity</th>
<th>Small to medium; that is up to 25,000 green tonnes per year of residue</th>
</tr>
</thead>
<tbody>
<tr>
<td>Feedstock requirements</td>
<td>Dry (Moisture Content 6 - 16% w.b.) Saw dust (particle size 3mm or less), chips and bark are also possible but require size reduction</td>
</tr>
<tr>
<td>Equipment</td>
<td>Grinder - for size reduction depending on size of feed material Classifier - particle size sorting Drier - moisture content reduction (depending on feed material) Material handling – May include feed hopper and conveyors Briquette Press/Extruder - compacts loose and fine wood particles into a dense body through the application of high temperatures of approximately 300 to 350°C and moderate pressure</td>
</tr>
<tr>
<td>Total plant cost</td>
<td>Grinder $2500 - 3500 Drier $3500 - 5500 Briquette Extruder $6500-8000</td>
</tr>
<tr>

</tbody>
</table>
## Wood Pellets

A solid fuel energy product that is easy to convey, transport and combust.

- Pellets have higher bulk energy density than sawdust or woodchips but lower energy density than liquid bio-fuels
- Pelletising plant involves relatively high initial capital outlay

| Typical plant capacity | Medium to large; that is typically greater than 25,000 tonnes per year of residues
| Feedstock requirements | Dry (Moisture Content less than 7% w.b.)
| | Saw dust (particle size 3mm or less), with minimal bark
| Equipment | There are a variety of configurations depending on supplier. Generally includes:
| | - Size reduction – grinder or hammer mill
| | - Drying – sometimes steam is used
| | - Homogenisation/classifier – Blending and sorting for size, sometimes combined with drying
| | - Press Rollers – high pressure and temperature (a starch binder may be required)
| | - Cooling tower- may be needed
| | - Materials handling – feed and product hopper
| Total plant cost | ~$1.5 million per tonne per hour
| Services | Electricity
| | Water (if steam drying is used)
| Operational cost | $120-160 per tonne including drying
| | $90-135 per tonne excluding drying
| Operational issues | Regular change out of dies due to wear
| Product | Robust, dense
| | Excessive handling makes them become dusty
| | Must meet AS/NZS 4014.6:2007
| | European standards are more stringent, particularly in terms of calorific value, ash and other contaminants contents
| | Quality Assurance testing and certification probably required for export
| Market | Very small market in Australia (no price data)
| | Sold in Europe for $100 to $350 per tonne
| Relevant incentive schemes (as of August 2007) | Industry Co-operative Innovation Program (Federal)
| | Climate Action Grants Program (NSW)
| | Regional Development Infrastructure Fund (SA)
| | Strategic Waste Initiatives Schemes (WA)
| Potential Suppliers | 1. International Renewable Biofuels – [www.irbf.net](http://www.irbf.net)
### Electricity generation – Steam turbine

An established, robust technology suitable for medium to large scale base load electricity production. Smaller systems may be viable with equivalent Organic Rankine Cycle (ORC) technology, which in essence replaces steam with a lower boiling point organic fluid as the heat transfer medium.

#### Typical capacity
Steam turbine generation is only suitable above ~5MWe although marginal proposition below 10MWe. ORC system can be viable down to around 1MWe.

Annual wood volume greater than about 60,000 dry tonnes per year, better above 100,000 dry tonnes per year.

#### Feedstock requirements
- Almost any feed with a positive net heating value is possible.
- Dirty or high alkali content feedstocks (eg, bark, sweepings, etc) can increase boiler scaling, contribute to clinker formation, increase ash production and create undesirable emissions. Generally, this will add cost to the system.
- Blend different residue streams to regulate composition and moisture content.

#### Main Equipment

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Materials handling</td>
<td>Larger systems generally employ conveyors directly from mill or stockpile via surge bin into combustor. Smaller system may be fed by front end loader. Tramp metal removal is advisable.</td>
</tr>
<tr>
<td>Pre-treatment</td>
<td>Dependant on furnace type and feedstock.</td>
</tr>
<tr>
<td>Combustor</td>
<td>Wide range of furnace types and configurations. Stoker-grate is advisable, for balance of cost and function. Staged combustion systems generally give higher efficiency and lower emissions.</td>
</tr>
<tr>
<td>Emission control</td>
<td>Baghouse filter probably required to reduce particulate emissions to &lt;100-250ppm (depending on location). Possibly scrubber or thermal oxidiser depending on fuel, combustor design and location.</td>
</tr>
<tr>
<td>Boiler</td>
<td>Water tube boiler with superheater. Economiser used for air pre-heat. Consider condensing economiser to increase heat recovery by condensing steam entrained in flue gas.</td>
</tr>
<tr>
<td>Turbine/genset</td>
<td>Condensing turbine for optimal efficiency.</td>
</tr>
<tr>
<td>Water purification</td>
<td>Commonly Reverse Osmosis (RO) plant, required to remove dissolved minerals and salts. Purity depends on boiler pressure.</td>
</tr>
<tr>
<td>Condenser</td>
<td>Usually part of condensing turbine unit unless backpressure turbine is used.</td>
</tr>
<tr>
<td>De-aerator</td>
<td>Used to remove dissolved gas from water prior to feed into boiler, reducing pitting corrosion inside boiler.</td>
</tr>
<tr>
<td>Cooling tower</td>
<td>Wet or dry. Wet towers will require water for evaporation. Dry towers are larger and require more parasitic power. Cooling pond is a possible alternative in certain circumstances.</td>
</tr>
<tr>
<td>Pumps/fans</td>
<td>For water return and blowing air</td>
</tr>
<tr>
<td>Grid interconnect (if required)</td>
<td></td>
</tr>
</tbody>
</table>

#### Total plant cost
$2-3.5million per MWe of installed capacity for new plant. It is possible to trade off efficiency for cost to reduce CAPEX, for example by reducing steam pressure, however these CAPEX savings generally result in increased operational costs.

#### Services
- Water for make-up in boiler (roughly 10% of steam flow rate);
- Fuel for start-up and peak load following through auxiliary burner;
- Chemicals for corrosion prevention in boiler;
- Grid connection with suitable level of excess capacity (if required).
### Operational costs

<table>
<thead>
<tr>
<th>Personnel</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Labour</td>
<td>Personnel may be required as follows: Technicians to monitor plant operation, fuel supply, emissions, etc; Mechanical/electrical fitters for maintenance and boiler blowdown; Boilers operators (depending on size and type of boiler – attended/un-attended); Supervisory or QA personnel; shift operation depending on degree of automation and attendance required.</td>
</tr>
<tr>
<td>Feedstock</td>
<td>Displacement cost for wood residue (lost revenue from other uses)</td>
</tr>
<tr>
<td>Maintenance</td>
<td>Rule of thumb 1.5% of CAPE X per year for mature technology. Can rise to 10% for less mature technologies</td>
</tr>
<tr>
<td>Water</td>
<td>Cost of water plus demineralisation</td>
</tr>
<tr>
<td>Chemicals</td>
<td>For corrosion prevention</td>
</tr>
<tr>
<td>Ash disposal</td>
<td>Dependant on feedstock (typically ~3%) to landfill</td>
</tr>
<tr>
<td>Parasitic power</td>
<td>Pumps, fans, conveyors, control systems</td>
</tr>
</tbody>
</table>

### Operational issues

Requirements for boiler attendance by ticketed operator depends on state legislation, but usually varies according to size of boiler:

- Small boilers (typically <10MWₚₜ) - Unattended operation permitted
- Medium boilers (typically 10-20MWₚₜ) - Limited Attendance required
- Large boilers (typically >20MWₚₜ) – Full Attendance required

Boilers require regular blowdown to remove scaling from heat transfer surfaces to maintain efficient operation.

### Product

Electrical conversion efficiency for a steam turbine system will be typically 15-25% (in size range up to 20MWₑ, generally efficiency increases with system size since parasitic losses become proportionally lower.

Use of waste heat (eg, in absorption chiller or heat exchanger) can increase overall system energy efficiency.

### Revenue

Ideally use to displace either grid procured electricity or a fossil fuel generator, to optimise economic benefit.

Can be sold to grid – this will earn wholesale price, grid operators prefer base load and will require a supply agreement. Government assistance is available, particularly in remote areas to encourage distributed generation.

### Potentially relevant incentive schemes

#### Federal
- Renewable Energy Certificates (REC)
- Low Emissions Technology and Abatement (LETA)
- Renewable Remote Power Generation Programme (RRPGP)
- Low Emissions Technology Demonstration Fund (LETDF)
- Renewable Energy Equity Fund (REEF)

#### NSW
- NSW Renewable Energy Certificates (NREC)
- Greenhouse Gas Abatement Scheme (GGAS)
- Climate Change Fund

#### SA
- Regional Development Infrastructure Fund (RDIF)

#### VIC
- Victorian Renewable Energy Certificates (VREC)
- Renewable Energy Support Fund (RESF)
- Sustainability Fund

#### WA
- Strategic Waste Initiatives Schemes (SWIS)

### Potential Suppliers

There are a large number of suppliers of biomass generation systems worldwide. Recent surveys have shown that many have little interest in supplying into Australia at present. Below is a list of potential suppliers who are active in the Australian Market:

1. Easteel – Braeside, VIC [www.easteel.co.nz](http://www.easteel.co.nz)
Electricity generation – Reciprocating Steam Engine

This is an established and robust technology that is good for small scale electricity generation, particularly with co-generation. Steam engines maintain relatively uniform efficiencies at high turn down and as such are well suited to variable demand applications.

<table>
<thead>
<tr>
<th>Typical capacity</th>
<th>Technology most suitable at sizes less than a few MW&lt;sub&gt;e&lt;/sub&gt; Or at an annual wood volume of less than ~50,000 dry tonnes per year</th>
</tr>
</thead>
<tbody>
<tr>
<td>Feedstock requirements</td>
<td>Almost any feed with a positive net heating value is possible. Dirty or high alkali content feedstocks (eg, bark or sweepings) can increase boiler scaling, contribute to clinker formation, increase ash production and create undesirable emissions. Generally, this will add cost to the system</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Main Equipment</th>
<th>Materials handling For small quantities, consider simple front end loader feed via surge bin into combustor.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pre-treatment</td>
<td>Trade-off between drying, size reduction and furnace/boiler cost. Simpler to dry within furnace by blending fuels to maintain average heating value. If climate permits and space is available, consider solar drying of green residues.</td>
</tr>
<tr>
<td>Combustor</td>
<td>Simple grate fired system to minimise cost. Travelling grate will increase fuel flexibility but add cost over stationary grate.</td>
</tr>
<tr>
<td>Emission control</td>
<td>Baghouse filter probably required to reduce particulate emissions to &lt;100-250ppm (depending on location). Possibly scrubber or thermal oxidiser depending on fuel, combustor design and location.</td>
</tr>
<tr>
<td>Boiler</td>
<td>Consider simple fire tube boiler for lower pressure systems to lower cost compared to water tube boiler. Slight degree of superheating of steam is best to prevent corrosion within engine. Consider economiser for water pre-heat from flue gases.</td>
</tr>
<tr>
<td>Engine/genset</td>
<td>Engines usually operate in backpressure mode since expansion to atmospheric pressure is costly. Ideal if steam at 1-2barg can be effectively utilised (consider use of steam accumulator to even out steam demand).</td>
</tr>
<tr>
<td>Water purification</td>
<td>Commonly Reverse Osmosis (RO) plant, required to remove dissolved minerals and salts. Purity depends on boiler pressure.</td>
</tr>
<tr>
<td>Condenser</td>
<td>Enables water to be pumped back into boiler. Not required if steam can be used and condensed as part of external process.</td>
</tr>
<tr>
<td>De-aerator</td>
<td>Used to remove dissolved gas from water prior to feed into boiler, reducing pitting corrosion inside boiler.</td>
</tr>
<tr>
<td>Cooling tower</td>
<td>Wet or dry. Wet towers will require water for evaporation. Dry towers are larger and require more parasitic power. Cooling pond is a possible alternative in certain circumstances.</td>
</tr>
<tr>
<td>Pumps/fans</td>
<td>For water return and blowing air</td>
</tr>
</tbody>
</table>

**Services**
- Water for make-up in boiler (roughly 10% of steam flow rate);
- Fuel for start-up and peak load following through auxiliary burner;
- Chemicals for corrosion prevention in boiler;
- Grid connection with suitable level of excess capacity (if required).

**Operational costs**
- Labour: Personnel may be required as follows: Technicians to monitor plant operation, fuel supply, emissions, etc; Mechanical/electrical fitters for maintenance and boiler blowdown.
- Feedstock: Displacement cost for wood residue (lost revenue from other uses)
- Maintenance: Rule of thumb 1.5% of CAPEX per year for mature technology.
- Water: Cost of water plus demineralisation
- Chemicals: For corrosion prevention – less than steam turbine system
- Ash disposal: Dependant on feedstock (typically ~3%) to landfill
- Parasitic power: Pumps, fans, conveyors, control systems

**Operational issues**
- Small boilers can generally operate unattended, provided size is less than legislated threshold for unattended operation (typically 10MW_e, but dependent on location).
- System can be made to operate automatically, provide fuel supply is maintained.

**Product**
- Electrical conversion efficiency for a steam engine system will be typically 10-15%, (operating in back-pressure mode).
- Good turn down efficiency results in good load following capability
- Use of heat will increase overall system energy efficiency.

**Revenue**
- Ideally use to displace either grid procured electricity or a fossil fuel generator, to optimise economic benefit.
- Can be sold to grid – will earn wholesale price, grid operators prefer base load and will require supply agreement. Government assistance available, particularly in remote areas to encourage distributed generation.

**Potentially relevant incentive schemes**
- Federal: Renewable Energy Certificates (REC)
- Low Emissions Technology and Abatement (LETA)
- Renewable Remote Power Generation Programme (RRPGP)
- Low Emissions Technology Demonstration Fund (LETDF)
- Renewable Energy Equity Fund (REEF)

- NSW: NSW Renewable Energy Certificates (NREC)
- Greenhouse Gas Abatement Scheme (GGAS)
- Climate Change Fund

- SA: Regional Development Infrastructure Fund (RDIF)

- VIC: Victorian Renewable Energy Certificates (VREC)
- Renewable Energy Support Fund (RESF)
- Sustainability Fund

- WA: Strategic Waste Initiatives Schemes (SWIS)

**Potential Suppliers**
- There is only one recognised supplier of reasonably sized reciprocating steam engines – Spilling Engine Systems – who are based in Europe, USA and Asia. A spilling steam engine is used by Big River Timbers, NSW, to provide heat and power for their sawmill operations. [http://www.spilling.de/uk/index-spillingwerk.htm](http://www.spilling.de/uk/index-spillingwerk.htm)
### Electricity generation – Gasifier and IC engine

Gasification systems coupled with IC engine/gensets are suitable for small scale electricity generation or cogeneration. These systems offer flexibility in terms of electrical (and thermal) load following. Availability is currently limited by reliable and verified gas clean-up systems.

<table>
<thead>
<tr>
<th>Typical capacity</th>
<th>Small scales, typically from 5kWe to 6MWe.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Feedstock requirements</td>
<td></td>
</tr>
<tr>
<td>• Low moisture content fuels are best, typically less than 15% w.b. Higher moisture contents impact gasifier performance and reduce energy content of syngas, reducing conversion efficiency.</td>
<td></td>
</tr>
<tr>
<td>• Size – Dependent on gasifier technology; typically uniform particle size is desirable for optimal gasification and to minimise particulate content in gas stream.</td>
<td></td>
</tr>
<tr>
<td>• Composition – Dirty fuels will increase ash content and ash removal rate and may impact on gas clean-up equipment.</td>
<td></td>
</tr>
<tr>
<td>Main Equipment</td>
<td></td>
</tr>
<tr>
<td>Pre-treatment</td>
<td>Depends on furnace type and feedstock, may include size reduction and drying.</td>
</tr>
<tr>
<td>Gasifier</td>
<td>Wide range of different furnace types and configurations. Small scale gasification is best suited to fixed bed rather than fluidised bed gasifier. Down-draft generally produces cleaner gas.</td>
</tr>
<tr>
<td>Gas train</td>
<td>Gas must be cooled before combustion in engine to increase gas density then filtered and scrubbed for particulates and tars. Each engine manufacturer will have its own strict requirements on gas stream composition (impacting energy content) and contamination.</td>
</tr>
<tr>
<td>Engine/genset</td>
<td>Essentially the same as a gas or diesel fuelled engine-genset.</td>
</tr>
<tr>
<td>Grid interconnect (if required)</td>
<td></td>
</tr>
<tr>
<td>Services</td>
<td></td>
</tr>
<tr>
<td>Back-up fuel (eg, natural gas or LPG) possibly for start-up and dual fuel operation for demand following</td>
<td></td>
</tr>
<tr>
<td>Grid connection (if required)</td>
<td></td>
</tr>
<tr>
<td>Operational cost</td>
<td></td>
</tr>
<tr>
<td>Labour</td>
<td>To maintain fuel supply, remove/dispose of ash and monitor gasifier and engine operation.</td>
</tr>
<tr>
<td>Feedstock</td>
<td>Displacement cost for wood residue (lost revenue from other uses)</td>
</tr>
<tr>
<td>Maintenance</td>
<td>Filters and scrubber maintenance heavily dependent on fuel used and gasifier characteristics. Usual engine/generator maintenance regime also required.</td>
</tr>
<tr>
<td>Fuel</td>
<td>For start-up and back-up supply</td>
</tr>
<tr>
<td>Operational issues</td>
<td>Main operational issue is cleaning gas and maintaining quality of gas entering engine. Gas train reliability testing is underway by many developers.</td>
</tr>
<tr>
<td>Product</td>
<td></td>
</tr>
<tr>
<td>• Electrical conversion efficiency is typically 5-15%. Generally efficiency increases with system size since parasitic losses become proportionally lower.</td>
<td></td>
</tr>
<tr>
<td>• Syngas may be directly combusted to provide process heat as required. Engine has fast response time to fuel supply.</td>
<td></td>
</tr>
<tr>
<td>• IC engine also has good load following ability, limited by gasifier response time unless dual fuel engine is used. Dual fuel may impact on incentive scheme eligibility.</td>
<td></td>
</tr>
<tr>
<td>• Waste heat from engine exhaust can be extracted via heat exchangers.</td>
<td></td>
</tr>
<tr>
<td>Market</td>
<td>Ideally use to displace either grid procured electricity or fossil fuel generator, to realise maximum economic benefit. Can be sold to grid – will earn wholesale price, grid operators prefer base load and will require supply agreement</td>
</tr>
<tr>
